No. 223.

PRESSURE RISES.

Inaugural Address by WILLIAM DUDELL, F.R.S., President.

(Address delivered 13th November, 1913)

Gentlemen,—In the first place I wish to tender to you my thanks for having again honoured me by electing me to be your President for a second year. During my year of office I think I may say that the Institution has prospered. The number of members has considerably increased and work has been initiated in many new directions. The Research Committee is now in working order and researches have been started or are under consideration on Permanent Magnet Steels, Heating of Underground Cables, Insulating Oils, and Wireless Telegraphy. The catalogue of the lending library is being prepared and country members will very shortly be able to borrow books which they wish to consult. The first number of our fortnightly *Journal* will be issued next month, and through it I trust that the Council may be able to communicate with the members much more frequently than in the past. For this reason, it is unnecessary for me to-night to refer at any length to the present or future work of the Institution.

Last year in my address I tried to draw your attention to various sections of electrical science and industry which I thought were being to some extent neglected by the Institution. This year I propose to revert to a practice which was much more frequent in the early days of the Institution, namely, to give you a more technical address.

PRESSURE RISES.

The subject that I have chosen, namely, "Pressure Rises," is one which is of interest to a very large number of the members because these rises, which occur under very varied conditions, are a source of trouble not only to the station engineer but also to the users of electricity, as they may endanger apparatus which is connected to the mains.

I must at once disclaim that the material I am bringing forward is novel. What I am endeavouring to do is to collect together and illustrate experimentally before you to-night many of the well-known causes of pressure rises.

Most of them are fully described in the literature on the subject, a list of which I give in an Appendix.

Under the heading of "Pressure Rises" I wish you to understand any rise in pressure above its normal value, but I propose to exclude from my address those accidental pressure rises which may occur should the speed of a generator become unduly high or should the current from a high-tension source get into a low-tension circuit, and to discuss those cases which take place during the apparently normal operation of the station or during faults on the mains.

The principal causes of pressure rises may be broadly divided into three classes:—

1. Resonance.
2. Switching.
3. Arcs and sparks.

1. RESONANCE.

An electric circuit which contains self-induction and capacity has, as is well known, a free period of its own, and electric oscillations may be produced in it provided that the resistance does not exceed a certain limit. If an alternator is connected to such a circuit, and if the period of the circuit is the same as the periodic time of the alternating E.M.F., then very violent oscillations may be set up in the circuit.

A limit to the strength of the oscillation is set by the apparent resistance of the circuit—by apparent resistance in this connection I mean a quantity which, when multiplied by the square of the current, gives the total losses in the circuit, including iron losses, eddy-current losses, etc., under the given conditions. For instance, if the apparent resistance R is comparatively small, then the voltage on the condenser or self-induction may rise to approximately $\omega L/R$ or $1/\omega CR$ times the E.M.F. of the alternator, where L is the self-induction, C the capacity, and $\omega = 2\pi f$, f being the frequency.

The most general case that occurs in practice is a long unloaded cable which is connected to an alternator. In this case the self-induction in the circuit is mainly the self-induction of the alternator itself. The capacity is the capacity of the cable, for unless the cable is very long it may be considered to act in just the same way as a condenser connected to the terminals of the alternator. In this very ordinary case resonance may be expected to take place if the period $1/f$ of the alternator is the same as the free period of the circuit. It may be thought that this case would occur very frequently, but it does not do so under normal working conditions.

It is easy to show that in order to obtain resonance at any frequency the capacity current taken by the cable under normal voltage must be equal to the short-circuit current of the generator at normal excitation and at the frequency considered. No station could very well be run in this condition, as it means that the capacity current of the cables considerably exceeds the normal output of the generator. Although I have observed many cases of resonance of a 3rd, 5th, 7th, and higher harmonics, I have seldom seen cases of resonance of the fundamental—one of them will be referred to later.

With regard to the question of the upper harmonics, if the wave form of the alternator is not a pure sine wave but is of such a shape that it may be considered to consist of a fundamental sine wave on which is superposed an alternating current having three, five, seven, etc., times the supply frequency, then the case is somewhat different, for although the resonance of the fundamental cannot take place, a resonance of one of the upper harmonics is quite possible, since it is evident that as the frequency increases the capacity current taken by the cable increases and the short-circuit current for that frequency decreases, so that they rapidly approach one another. For instance, if the normal capacity of the cable were, say, $\frac{1}{10}$ th of the short-circuit current of the alternator, then a resonance of the 3rd harmonic takes place if such a 3rd harmonic exists in the wave form. If the ratio were $\frac{1}{25}$, then the 5th harmonic might resonate. Now the ratio $\frac{1}{25}$ is quite a possible condition, for this roughly corresponds to the capacity current in the cables being about $\frac{1}{15}$ th of the full-load current of the alternator, so that resonance of the 5th and higher harmonics may be expected in practice. Whether they are serious or not will largely depend upon the magnitude of these harmonics in the wave form of the alternator.

* Let E be the E.M.F. of the alternator,

f = frequency,

$\omega = 2\pi f$,

L = self-induction of the alternator,

C = capacity of the cable,

I_s = short-circuit current of the alternator determined in the usual way,

I = capacity current of the cable.

As a first approximation the resistance of the alternator and cable will be neglected. Then the short-circuit current of the alternator

$$= I_s = E / \text{Impedance} = E / \omega L.$$

The capacity current into the cable $= I = E / \omega C$.

$$\therefore I_s I = L \omega C \omega.$$

For resonance $I = 2\pi \sqrt{LC}$, or $LC = (1/2\pi f)^2 = 1/\omega^2$,

$$\text{or—} \quad L \omega C \omega = 1,$$

$$\therefore I_s I = 1.$$

With modern alternators resonance seems to have practically disappeared in this country. In the early days I had some bad cases to investigate when resonance of one or other of the harmonics took place, which either caused failures or difficulties in regulating the voltage. With the modern machines the 3rd, 5th, and 7th harmonics are generally so small that there is no trouble from their resonating. Resonance of the higher harmonics is more likely to take place, but owing to the very much greater losses due to eddy currents, hysteresis, etc., the resonance of these higher harmonics does not in general attain a serious magnitude, especially if there is any load on the machine.

There is one point which it is necessary to bear in mind in connection with the possibility of resonance of one of the higher harmonics. It is quite true that in the ordinary three-phase systems the wave forms between the phases are practically free from the 3rd harmonic, but this is not necessarily true of the wave form between each of the terminals and the neutral point. Care must therefore be taken that the resonance of this harmonic does not occur. From this cause there might be quite a considerable potential difference between each of the cores of the cable and earth, whereas a record of the wave form taken between the cores might show nothing abnormal.

As a few examples of resonance of the higher harmonics observed in generating stations when the alternators were connected to feeders on open circuit, the following may be of interest.

Fig. 1 is the open-circuit wave of an old type of 400-kw. 2,000-volt alternator, and Fig. 2 is for the same machine connected through a 3:1 transformer to two of the feeders. The record which was taken on the high-tension side of the transformer shows a marked resonance of the 3rd harmonic, causing the potential-difference wave to fall almost to zero once during each half-period. The maximum volts are 10,140, or 1.60 times the R.M.S. value instead of 1.41 times for the sine wave. This is quite an exceptional case owing to the shape of the open-circuit wave and the large capacity of the cables in comparison with the size of the machine.

Fig. 3 shows the open-circuit wave of a more modern 500-kw. three-phase 6,600-volt generator, and Fig. 4 is for the same machine connected to two of the feeders. A resonance of the 13th harmonic has taken place and the maximum voltage has risen to 14,000, or 2.33 times the R.M.S. value.

As a further example of a resonance of a 13th harmonic, Figs. 5 and 6 show the potential-difference waves of a 1,500-kw. three-phase 6,600-volt alternator on open circuit, and with cables connected; the peak of the pressure curve in this case is 12,900 volts. Figs. 7 and 8 refer to the same case recorded between one terminal and earth.

The effect of the changes in speed on the wave form near a resonance is exemplified in Fig. 9, which shows the open-circuit wave of a 330-kw. 5,000-volt generator at normal speed, and in Fig. 10 for the same machine connected to four feeders. An increase of 8 per cent in the speed produces Fig. 11, and a reduction of 26 per cent Fig. 12.

The importance of the observation is that alternators should never have their speed run up or down when excited and connected to cables on open circuit, for fear

of passing through a possible resonance of an upper harmonic. In this connection I should like to draw attention to the case of switching off at the generating station a feeder connected at its far end to a running motor or rotary converter. When the switch opens, the cable is left

off together at the generating station, giving a very considerable rise in pressure on the feeder.

A similar case is shown in Fig. 14, in which a feeder supplying two motor-generators in a sub-station was disconnected from the busbars by tripping the oil switch. The

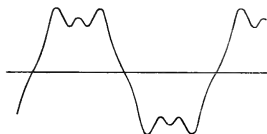

FIG. 1.

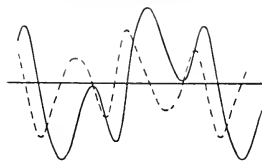

FIG. 2.

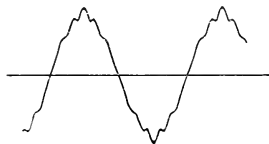

FIG. 3.

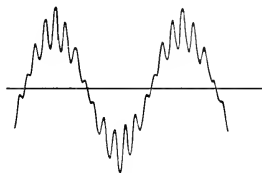

FIG. 4.

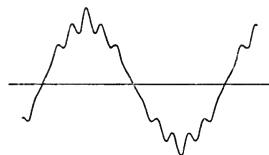

FIG. 5.

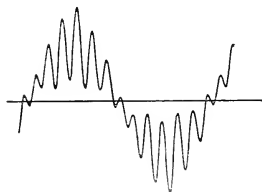

FIG. 6.

FIG. 7.

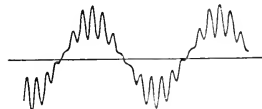

FIG. 8.

connected to the running motor or rotary converter which acts for a short time as a generator. As the machine slows down there is a considerable risk of a resonance, the more so as the self-induction of the motor or converter may be high enough to give a resonance even of the fundamental. An example of this effect is shown in Fig. 13, where a 500-kw. rotary converter and feeder have been switched

off together at the generating station, giving a very considerable rise in pressure on the feeder.

I have already mentioned that in order to get resonance

the cable system should be on open circuit. If the cable system has a number of transformers connected to it, the secondaries of which are on open circuit, the risk of resonance is still present because the magnetizing current taken by the high-tension side of modern step-down transformers is so small as hardly to affect the conditions. Directly there is any appreciable load on the system the risk of a serious resonance becomes very small and rapidly vanishes.

the best method of illustrating this is by an actual example. A three-phase voltmeter transformer was connected to the busbars on the high-tension side by means of a fairly long length of cable. At the busbar ends of the cable were links which could be withdrawn in order to disconnect the transformer when required.

In this case it was found that if one of the links at, say, *b* (Fig. 15) were in place, the other two being open, a high

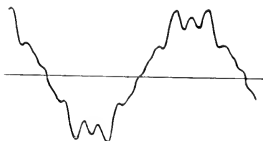

FIG. 9.

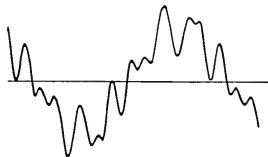

FIG. 10.

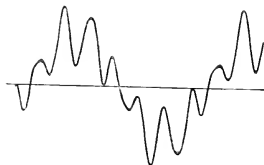

FIG. 11.

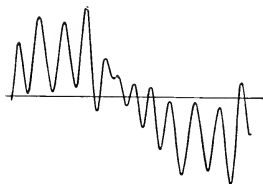

FIG. 12.

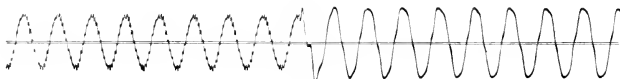

FIG. 13.

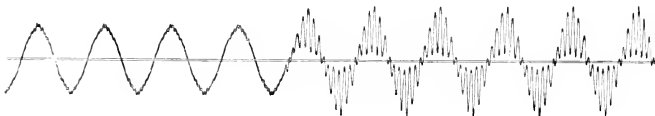

FIG. 14.

It is necessary to point out that should, owing to any cause, the load be suddenly switched off the ends of long feeders so as to leave them unloaded and connected to the generator there is the probability of a pressure rise due to the combination of resonance, a rise in the speed of the generator, and interrupting the current, referred to below under "Switching."

There are certain special cases in which resonance of the fundamental may appear in unexpected ways. Perhaps

voltage occurred between either of the other terminals and earth.

The neutral point of the generator was earthed, and each of the cables between the busbars and the instrument transformer had a capacity of about $\frac{1}{100}$ mfd. to earth. A circuit was thus formed through the closed link *b*, two coils of the transformer in series, and the capacity of the lead to earth, back to the neutral point. The self-induction of the two coils of the transformer in series was just about sufficient

to give a resonance when in series with the capacity of the cable to earth at the ordinary working frequency. The voltage, which should have been 4,620 (8,000 volts between phases) between *a* or *c* and earth was observed to be 10,100, or more than double the proper value. On disconnecting the pieces of cable between *a* and *c* and the transformer, the observed voltage on the open legs of the transformer fell to 4,700, practically normal value. Every time a voltmeter transformer was put in or out of circuit by withdrawing the link, the somewhat dangerous condition had to be passed through where one of the legs of the transformer was submitted to something like twice the normal pressure.

As another possible example take the case of a 100-kw. single-phase transformer supplied at 6,000 volts through a feeder one mile long and feeding into a distributing net-

work. In order to avoid discussing the properties of long cables twice over.

Summing up, it may be said that resonance at the fundamental frequency is rare but very dangerous when it does occur.

Resonance of an upper harmonic is much more frequently observed, but with the good wave forms of modern turbo-alternators the amplitudes of the upper harmonics are so slight that their resonance does not generally produce any dangerous pressure rise.

2. SWITCHING.

In switching apparatus in and out of circuit there are a certain number of cases in which the pressure may rise considerably above the normal irrespective of any arcing or sparking which may take place at the contacts. The

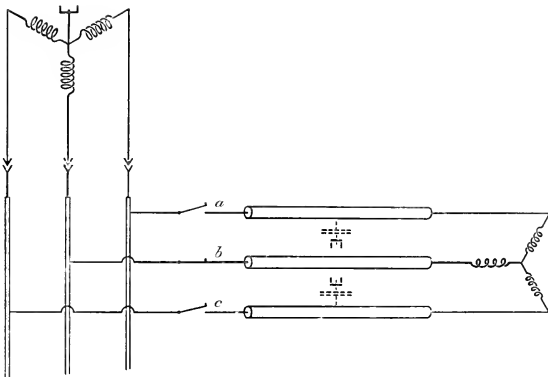

FIG. 15.

work. If the capacity of the feeder be taken as 0.25 mfd., the capacity current at 50 frequency will be just under $\frac{1}{2}$ ampere. The magnetizing current of the primary of this transformer may not differ much from $\frac{1}{2}$ ampere, and there is thus a possibility of a pressure rise should the feeder be disconnected at the generating station, leaving the transformer connected on the low-tension side transforming up and making the cable alive. If there was much magnetic leakage in the transformer this rise might be serious.

In two-phase or three-phase systems a number of combinations of the cables and transformers exist where, if a connection be opened, or during switching, the self-induction of the transformers may be in series with the capacities of the feeders, as pointed out by Steinmetz.

The resonances that may occur between the distributed self-induction and capacity of long cables causing rises of pressure at their ends, generally known as the "Ferranti effect," will be referred to later under "Switching" in

best known is probably the ordinary case of opening an inductive circuit such as the field coil of a generator. If the rate at which the current is suppressed is sufficiently great, very high voltages can be produced, because the whole of the energy that is stored in the self-induction is set free, and must be either dissipated or stored in some available condenser. If an uncharged condenser is suddenly switched on to a generator, then in the general case the potential difference between the terminals of the condenser will rise not only to that of the generator but will overshoot the mark, and may, in the extreme case if there are no losses, reach twice the value. This is analogous to the ordinary case of the ballistic galvanometer in which, when the damping is small, the initial deflection on switching it into circuit is twice the steady deflection.

We have here, therefore, two fundamental cases where pressure rises may easily occur in practice, namely, when inductive circuits are suddenly opened or when condensers such as cables are suddenly charged. The simple case of

the inductive circuit it is well known that nothing more need be said about it except to point out that in the case of long feeders where the currents are large the energy stored in the self-induction of the feeders may be quite considerable; this is especially the case with continuous-current feeders.

As examples of the voltage rise when switching on a capacity, Fig. 16 shows the case of switching on and off 3 miles of cable on open circuit at 5,600 volts to a 1,000-kw. generator by means of an oil switch. The peak of the potential-difference curve is 14,500 volts, or about 2.6 times the R.M.S. value. The switching off of the cable gives no rise, the cable behaving like a simple concentrated condenser. The fine ripples on the curve are due to a high harmonic slightly resonated.

As another example, Fig. 17 shows the switching on and off of about 2 miles of cable by means of an air-break switch from a 5,000-volt generator of an old type which had not a very good wave form. At the moment of switching

$2(V + v)$, or the voltage rise measured from the zero line, $2(V + v) - v$, say $2V + v$. In the worst case of $v = V$ we have a maximum of $3V$; or for a sine wave say 4.2 times the R.M.S. voltage.

I have already stated that no rise of potential takes place when switching off a condenser. If, however, sparking or vibration takes place at the contacts the effect just mentioned may occur. Fig. 17 is a good example where the cable was switched off from the machine, and it shows that while the cable was discharging after the first switching off the switch re-made contact again and re-charged the cable in the reverse direction. During the following discharge the switch again made contact and re-charged the cable, giving a pressure rise to 12,000 volts. The switch now finally breaks contact and the cable discharges with a tendency to a slow oscillation.

A bad case of vibration of the contacts of switching combined with a resonance is shown in Fig. 18, in which about 12 miles of feeder were switched on to the 400-kw.

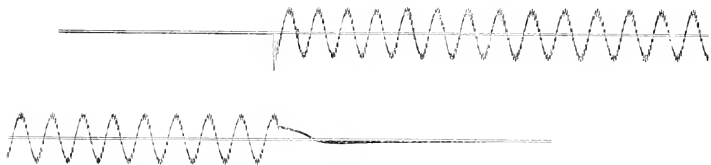

FIG. 16.

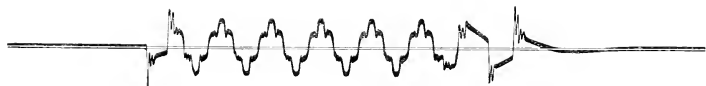

FIG. 17.

on the potential difference rose to 11,000 volts, or 2.2 times the R.M.S. value. It is to be noted that after the first contact at the switch the cable becomes charged by the oscillations. The switch then breaks contact and the charge in the cable leaks away through the oscillograph giving part of a discharge curve. About $\frac{1}{10}$ of a second later, while the cable is still partly charged, the switch makes contact again and the cable is re-charged, but this time in the reverse direction, from the following half of the wave form. The cable again becomes charged by the oscillations and finally settles down.

This effect of a switch not making perfect contact may lead to high pressures, because the upper limit to which the voltage on the condenser may swing is twice the difference of potential which is suddenly applied to it. For instance, if after the first contact the cable is left charged to a potential $+v$ and then contact is made again at the middle of the following half-period when the voltage is $-v$, the change of voltage applied to the condenser is $V + v$, and the first swing may amount to

generator already mentioned (see Fig. 1). The cable was not quite discharged from previous experiments at the moment the switch made contact. The ordinary rise, but not a serious one, took place, and the switch remained closed for little over half a period. It then broke contact for approximately half a period; after which it re-made contact, giving a high rise in the reverse direction to 5,100 volts from a R.M.S. value of 2,000. During the next half-period the switch appears to have made good contact, but during the following one it has again been faulty in its contact. The moral is: Use a switch which closes quite clean without any chattering of its contacts, and switch on under oil, as the risk of a leading spark is thereby greatly decreased.

The smaller curve is the current flowing into the cable, which current it will be noticed has three times the fundamental frequency, owing to the fact that the conditions are practically the conditions of the resonance of the third harmonic of this machine already referred to. The results of a very large number of tests of switching on and

off cables on open circuit show that in general on switching on the cable, if no sparking takes place, the peak rarely exceeds twice the R.M.S. voltage, and that there is no rise on switching off. If, however, vibration of the contacts takes place or sparking, which will be referred to again later, then the peak may be more serious. If the switch is in good condition, however, the upper limit of the peak may, I think, be safely taken at three times the R.M.S. voltage.

As all cables and apparatus should at least be able to stand safely twice the working voltage for short periods, to switch on a cable should be quite safe provided no serious sparking takes place at the contacts.

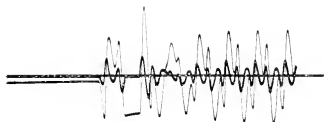

FIG. 18.

I have so far mentioned the cases of a capacity or a self-induction, *i.e.* a cable or a winding of a machine suddenly switched in or out of circuit. The next case is the switching in and out of a circuit which has both capacity and self-induction; in this case oscillations may be produced if the resistance is low enough. Assume for the moment that the capacity and self-induction are not distributed, that is to say, can each be considered to be situated at the point in the circuit, for instance at C and L in Figs. 19 and 20.

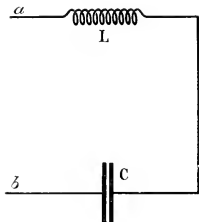

FIG. 19.

I will consider the effects according to whether a generator with a fixed voltage and with no self-induction or capacity is suddenly connected or disconnected between *a* and *b* (Fig. 19 or Fig. 20), *i.e.* the series or parallel arrangements. If the generator be suddenly switched in between *a* and *b* (Fig. 19) the charging current of the condenser will flow through the self-induction, storing energy in the magnetic field. At the moment when the condenser is fully charged, this stored energy will tend to maintain the flow of the current, and so overcharge the condenser, followed by the usual oscillations if the resist-

ance is low enough. The upper limit of the voltage applied to the condenser, assuming that there are no arcs or sparks at the contacts, is twice the voltage impressed by the generator, but this is not attained in practice owing to numerous causes which dissipate the energy. The equation representing the voltage during the charging of the condenser is—

$$V_t = V_g (1 + e^{-at} \sin ft),$$

in which V_g is the E.M.F. of the generator and V the potential difference between the terminals of the condenser. The constant $a = R/2L$ is the log. decrement, and $f = 2\pi/L$, where f is the frequency of the free oscillations in the circuit. This is the ordinary case of switching in a condenser, say a cable, and the limiting value of the pressure, *i.e.* when $fL = \pi/2$ (if no sparks or arcs occur, see later), is twice the machine voltage. It is to be noted that if the self-induction of the circuit could be made really nil there would be no rise; but this case is never obtained in practice.

On breaking the connection the condenser remains charged, and no pressure rise takes place. If the points

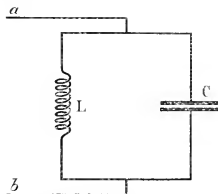

FIG. 20.

a and *b* be short-circuited the condenser will discharge through the self-induction, possibly with oscillations, but no rise will take place.

If the generator be suddenly switched without sparking on to the points *a* and *b* (Fig. 20), *i.e.* in parallel with the self-induction and the condenser, the condenser will be charged and the current will grow through the self-induction without any pressure rises owing to the assumed fixity of the voltage of the generator—as a generator with no self-induction does not exist the absolute fixity of the applied voltage is impossible, so some small initial rise may take place in practice. On switching off, on the assumption that no sparking or other form of dissipation of energy takes place, the whole of the energy stored in the magnetic field of the coil *L* is suddenly liberated, and must be transferred to and stored in the condenser. If the current through the self-induction be *I*, then the stored energy is $\frac{1}{2} LI^2$. If the voltage between the terminals of the condenser be *V*, the stored energy is $\frac{1}{2} CV^2$. These two quantities have to be equal if the energy is assumed to be transferred from the magnetic form to the electrostatic form without losses.

Hence—

$$\frac{1}{2} LI^2 = \frac{1}{2} CV^2, \text{ or } \frac{V}{I} = \sqrt{\frac{L}{C}}.$$

If the ratio L/C be known, then the limiting voltage corresponding to any current can at once be determined. For example, assume the self-induction of the generator to be 5 millihenries, and the capacity of two miles of cable to be $\frac{1}{2}$ mfd., then $L/C = 10,000$ and $\sqrt{L/C} = 100$. Therefore if 1,000 amperes were suddenly interrupted at the end of the cable, a pressure of 100,000 volts might be produced. Owing to the spark at break, and the iron losses, leakage, etc., so high a voltage is not actually obtained.

The mathematical treatment of the general case of a long cable having distributed resistance, self-induction, capacity, and leakage, is somewhat difficult to follow in all its details. Dr. Kennelly's treatment of the subject by means of hyperbolic functions in a series of lectures given in this room enables a great many of the properties of these cables to be readily understood, and when the complete set of tables of the hyperbolic functions of imaginary quantities which Dr. Kennelly is preparing are finished, the labour of calculating any special case will be considerably reduced. For the present purpose of considering pressure rises most power-supply cables may be looked upon with sufficient accuracy as approximating to the two limiting cases of very short or very long cables. This leads to a great simplification of the discussion. For accurate prediction of the voltage drop and other properties of long lines, and also in telegraphy and telephony, these approximations are not permissible. A further simplification can be made if leakage be neglected, which is generally the case. Its effect if present will be to reduce rather than to increase the pressure rises.

Consider an infinitely long cable and let it be suddenly connected to an alternating-current generator at the moment when the potential difference is zero. As the potential difference increases at the generator end of the cable a current will flow into it charging up the condenser formed by the cable and earth, and this charge will travel along the cable with a certain velocity. Owing to the resistance and capacity of the cable the quantity of electricity flowing along it will become less and less as the charge travels along, so that one may look upon the wave travelling down the cable as being of continually decreasing amplitude. As the wave travels down the cable with a certain velocity the alternator continues to revolve, that is to say the phase of the current wave applied to the end of the cable is continually changing, so that the phase difference between the alternator wave and the current wave travelling down the cable increases progressively. The net result is that in a very long cable the wave travelling along the cable continually diminishes in amplitude and lags behind the generator in phase.

If the cable is electrically very short there will be practically no diminution in amplitude or change of phase while the wave progresses along it. This is in general the case for the underground cables and power lines in this country at ordinary frequencies, and under these conditions the cable may be considered to be replaceable by an equivalent arrangement of self-inductions and condensers, as shown in Fig. 21, in which the capacity of each of the two condensers is equal to one-half of the capacity of the cable, and the self-induction and resistance of the coil between them are equal to the self-induction and resistance of the whole cable. The pressure rises that may occur in this cable are approximately those already referred to

when dealing above with localized self-inductions and capacities.

Very long lines, such as those in use abroad, cannot be considered quite so simply. Suppose a long line is on open circuit at the far end, and, as before, it is suddenly connected to the generator at the zero point of the potential curve. Then the wave of current flows down the line, and when it gets to the open far end it is reflected or turned back on itself and flows back towards the generator; now at this reflection at the far end, the potential difference of the wave is doubled. The wave now travels back towards the generator, where if the generator is assumed to be very large the wave will go to earth quite freely and the reflection will take place with a reversal of phase and no increase in amplitude. The current wave will again travel back towards the far end of the cable where it will again be reflected, and it will travel successively backwards and forwards and so build up to the steady state. Consequently in the steady state of such a cable the voltage of the far end may be looked upon as being built up on a number of components of different phases. The magnitude of the voltage will naturally depend upon the phases and magnitudes of these components. First as regards their magnitude; as the charge travels along the cable the voltage decreases according to an exponential law—

$$V = V_0 e^{-\alpha L}$$

in which α is the attenuation constant. For instance, in a certain cable the quantity $e^{-\alpha L}$ might at a given frequency be 0.7. This would mean that the voltage at the far end was only 70 per cent of that suddenly applied by the generator, so that in transmission along the cable the first time there is a loss of 30 per cent. This wave is reflected as already mentioned and travels back towards the generator, where it arrives again reduced by 30 per cent, that is to say to 49 per cent of its initial value; the reflection then takes place at the generator and the wave travels back, arriving at the far end with about 35 per cent of its initial amplitude. This adds on vectorially to the initial wave so that the waves at the far end of the cable are a summation of a rapidly diminishing series of waves.

The phases and amplitudes of the components of the voltage at the end depend upon the frequency, the length of the line, and its constants. In order that the components may add up to a considerable total it is necessary that they should all arrive at the far end in the same phase, or more accurately that the phases should differ by a multiple of 2π . As the reflection at the generator end is accompanied by a reversal of phase the travel of the wave along to the end and back must be accompanied by a change of phase of π , i.e. the alternator must have changed its phase by $\pi/2$ during the time the wave takes to travel along the line, which means that the length of the line is a quarter of the wave-length at this frequency. This condition leads to a building up of the potential at the end of the line.

Another way of looking at the effect is to consider that the wave which is started flows along the line and after reflection at the open end returns to the generator, where it should arrive at the moment that the alternator has reversed the direction of its E.M.F., so that the returning wave and the E.M.F. of the alternator act in the same direc-

tion and assist one another. This effect, namely the building up of the potential at the far end of the line on open circuit, is generally known as the Ferranti effect, owing to its having first been observed by Dr. Ferranti on the Deptford mains.

In general the velocity of propagation of the wave along the line is less than the velocity of light, say from one-quarter this velocity upwards for ordinary cables and lines, though nearly equal to it for straight wires in space away from other bodies.

At 50 frequency with a cable having a self-induction of 0.5 millihenry per mile and a capacity of 0.25 microfarad per mile the velocity of propagation is about 86,000 miles per second in round figures.

Hence the distance travelled in one-quarter period, or one two-hundredth of a second, is 430, so that the quarter of a wave-length will correspond approximately to 430 miles.

With higher frequencies the length to produce the effect is considerably shorter, so that the effect can become quite marked with the upper harmonics and moderate lengths of circuit, and considerable rises of pressure due to this cause have been observed in the United States.

It is well to point out that a load on the end of the line

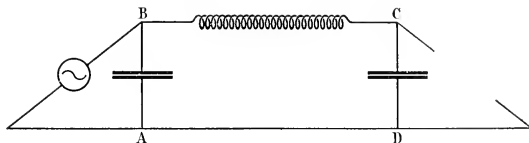

FIG. 21.

reduces the effect, so that on loaded lines it soon becomes inappreciable.

With the higher frequencies employed in wireless telegraphy the Ferranti effect is very marked. Aerials are always adjusted with their added self-induction to the quarter wave-length, so that the potential at the free or open end may amount to some hundred times the pressure employed at their base.

With the short cables in use in this country the effect is rarely observed, but it is of considerable importance from the point of view of the sparking and arcing that may take place in switching operations and during faults, which may generate oscillations of a suitable frequency to produce the effect to a very marked degree with comparatively short leads. The magnitude of the effect depends on the resistance being small, which is generally the case in practice.

In making calculations of the frequency which will produce the Ferranti effect on very short lines, the line may be considered to be replaced by the circuit shown in Fig. 21, as pointed out by Dr. Kennelly, and the frequency of resonance of the part B C and D may be calculated by the simple Kelvin formula. A more accurate result can be obtained for short lines of small resistance by taking $2/\pi$ of the capacity and $2/\pi$ of the self-induction of the whole line, and calculating the free period of a circuit composed of a capacity and self-induction having these values.

Some very interesting cases occur when inductive windings are suddenly switched into circuit; for instance, the high-tension coils of transformers, induction motors, or any alternating-current apparatus. In this case there may be no observable pressure rise between the terminals of the coil, but yet during the initial stages the full pressure which is applied between the terminals of the coil may be so unequally divided between the windings as to produce locally differences of potential far above the normal.

Let us consider the coil shown in Fig. 22, and let us assume that a high voltage V is suddenly applied to it by means of the switch s . Now in the steady state the voltage V will be assumed to be uniformly divided among the turns of the coil, so that between the ends of the first turn there will be V/n volts, if n is the number of turns. Now consider what happens at the first moment of closing the switch s . The current will not instantly attain its steady value; there will be a preliminary stage, and during this preliminary stage one may imagine that a quantity of electricity is travelling forward along the coil from its end. In other words, that there is a sort of wave front starting from the switch to travel along the coil similar to the charge of a long cable. If the coil possessed no electrostatic capacity, i.e. no condenser action, either from turn to

turn or from turn to earth, the current would be propagated instantaneously round the coil, and would start to grow from zero in all parts of the coil equally at the same time; but in practice this is never the case, for every coil, however made, possesses some finite though very small condenser action. The wave front therefore takes some appreciable time to travel round the coil, although this time may be exceedingly small. During this progress the potential difference is by no means uniformly distributed along the coil; in fact, the coil may be looked upon as similar to a long submarine cable if one remembers that the electrical constants are very different, and consequently the times of propagation of the disturbance.

In the case of a submarine cable, say an Atlantic cable, if the voltage is suddenly applied at this end, the wave starts off and travels towards the States, and the first trace of its arrival occurs rather less than 0.1 sec. later. In the case of the windings of an ordinary transformer the length of time required for the wave front to travel along the coil is probably less than $1/100000$ th of a second. In both cases during the initial stages practically the whole of the potential difference is localized.

The localization of the voltage on the turns of a transformer at the moment of switching it into circuit is of great practical importance and is the cause of many failures. The effect is further aggravated by any sparking which may take place at the switch contacts, which

sets up high-frequency oscillations in the leads connected to the transformer. As the high voltage between turns due to switching in only lasts a very short time, too short to be recorded by an ordinary oscillograph, the failure of the insulation between turns may only take place after a number of switchings, when the insulation between turns having been locally weakened, heating sets in at the normal working voltage and a breakdown of the coil to earth soon follows. For this reason extra insulation is often placed on the end turns of transformers, or choke coils are used in series with them as a protection.

High-voltage motor windings are subject to a similar effect, and with asynchronous motors there is a further possible cause of localization of the pressure on a limited number of turns of the windings, not necessarily the end turns. This depends on the fact that the self-induction and mutual-induction of the different sections of the windings are not necessarily equal, owing to the mechanical difficulties in making the short air-gap perfectly equal all round the machine.

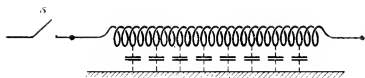

FIG. 22.

The localization effect on the end turns of the apparatus is especially noticeable in connection with the high-frequency oscillations or with the steep wave front currents which may travel along overhead lines after lightning discharges. These are very similar in their properties, but, owing to the much higher voltages which may be induced, much more destructive and difficult to guard against than the steep wave fronts and oscillations that can be set up by switching on apparatus. This effect has been investigated by Jackson.

Switching off ordinary loads is generally safe, for even should the switch try and open the circuit when the current has its maximum value it is improbable that the rate of decrease of the current will be sufficient to produce dangerous pressure rises. On the other hand, abnormal currents and short-circuits may give rise to excessive pressure, as the energy liberated at the break is so large that it may form an arc and blow the switch to pieces. If the rate of break is sufficiently rapid to avoid this, the rate of change of the current may be so great that a dangerous pressure rise is produced. A number of valuable records showing the switching off of large powers amounting to tens of thousands of kilowatts are given in a paper by Marguerre in which practically no rises of pressure are observable, but I think it is unwise to assume that this is always the case. The best means to employ to limit the short-circuit current of generators is one of the problems which faces designers at the moment, both to protect the machines themselves from damage and to reduce the risk of pressure rises on opening the circuit.

The whole question of the rate of change of current that may take place at the moment of switching off is really a question of the suddenness with which the arc or spark between the switch contacts can be extinguished, for except under very exceptional cases it is impossible to

break any considerable current without some arc or spark forming at the contacts. The rise due to these causes will, however, be considered in the next sections.

3. ARCS AND SPARKS.

Pressure rises may in many cases be traced to the properties which arcs and sparks have of facilitating or causing rapid rates of change of current. The properties of an electric arc are somewhat peculiar in that it is one of the few electric conductors which is in general essentially unstable. By this I mean that if the current be increased through an ordinary arc the potential difference between its terminals decreases, producing a further tendency for the current to increase, which if it is not limited by some other resistance in the circuit would tend to increase to an unlimited extent. On the contrary, if the current be decreased the potential difference between the terminals of the arc rapidly rises, tending to suppress the current altogether. In fact, it is quite well known that it is necessary to have a steady resistance or its equivalent in series with any arc in order to reduce the tendency of the current to go off suddenly to infinity, or to become zero.

This instability of the arc favours the sudden suppression of the current should an arc be formed, and tends to produce pressure rises if there is any self-induction in the circuit, which in practice is always the case. The instability of the arc may be greatly increased if the electrodes are kept cool; for instance, if they consist of large masses of good heat-conducting material. Further, this effect is increased if the electrodes are close together so that they tend to cool the vapour column of the arc. A transverse magnetic field also makes the arc unstable. Shunting the arc with a condenser greatly increases this instability, because should the current through the arc decrease due to any accidental cause the potential difference between the terminals of the arc will increase. This will tend to cause the current to flow into the condenser shunting the arc, which current will be diverted from the arc. It should therefore tend to reduce still further the current through it, rendering the conditions more unstable than without the condenser as a shunt.

A great deal has been written about the difference between arcs and sparks. In my mind the fundamental difference between an arc and a spark is that in the arc the electrodes are being continuously volatilized, and the vapour of the electrodes takes part in the passage of the electric current. The spark, however, is generally of an intermittent or a transitory nature, the electrodes are not appreciably volatilized, and the current is largely transferred through the air. It is pretty obvious that there cannot exist any clear line of demarcation between the two phenomena, and that the one merges into the other under the above definition, depending on the mass of volatilized electrode present in the vapour column. The properties of the spark are more difficult to investigate than those of the arc owing to its transitory nature, but there seems little doubt that they are essentially similar with regard to instability. In fact there are reasons to suppose that the electric spark possesses the same instability as the arc but in an enhanced degree.

Any arcing or sparking taking place in a circuit is liable to set up oscillations which may give rise to dangerous

pressure rises. It is therefore necessary to consider the types of oscillations which may be produced by arcs or sparks. The best-known case is the oscillatory discharge or charge of a condenser such as is used in wireless telegraphy. Fig. 23 shows the usual connections.

If the source of supply is high-tension alternating, each time the condenser charges up to a sufficient voltage the gap s will break down and an oscillatory discharge will take place. This discharge repeats itself each half-wave, or several times per half-wave if the conditions are suitable. The activity of the oscillations depends very much on the condition of the spark at the gap s . If a lot of conducting vapour is formed, or if the electrodes remain very heated so that the gap does not recover its insulating properties very quickly, then after the first discharge the condenser cannot be charged to so high a voltage, and the activity of the oscillations falls off.

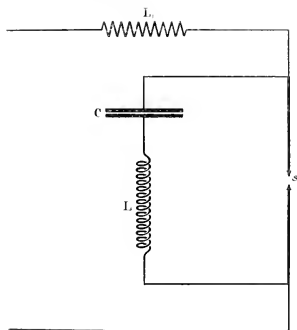

FIG. 23.

For this reason sparks taking place between large masses of metal which are good conductors of heat or in a magnetic field are more likely to be active than those that take place between carbon electrodes. If after the spark takes place the generator current follows, forming an arc and a quantity of vapour, the oscillations are generally reduced in activity.

If the supply is continuous current, oscillations can still be produced provided that the arc is such that $\partial V/\partial I$ is a negative quantity, where ∂V is the change in voltage produced by a small change ∂I in the current through the arc, and that the resistance of the oscillatory circuit composed of L and C is low enough. The quantity $\partial V/\partial I$ is not in general negative for large-current arcs in air, so oscillations due to this cause do not seem probable at first sight. Large-current arcs in gas and in magnetic fields can, however, produce powerful oscillations. Further investigation is required as to whether under the initial conditions of the formation of large-current arcs the instability may not be such that oscillations can be produced.

A water model can be made which will to some extent indicate the instability of the arc and will give a good

representation of how the oscillations are produced. In the actual model the arc is represented by a mushroom valve. The pressure of the valve on its seat is so arranged that the pressure tending to reseat the valve diminishes very rapidly as the valve lifts. Water is admitted beneath the valve, flows through the valve into the vessel which contains it, and overflows. In order to indicate the difference of pressure on the two sides of the valve which represents the arc a glass pressure-column is introduced into the pipe leading to the valve and quite close to it. As the water overflows freely from the tank in which the valve is immersed, the pressure on the side of the valve may be taken as our zero of reference, and consequently the height of the water column in the pressure tube above or below the level of the overflow gives the pressure underneath the valve.

If water be admitted from the tank below the valve the pressure in the pressure tube rises to a high value; finally the valve lifts, i.e. the arc is struck, but the pressure still remains high. If, however, the flow of water is increased, the valve will open considerably and the pressure below it will decrease. If nicely adjusted this effect can be made to take place over a considerable range.

If instead of connecting a pressure tube of small bore indicating the pressure on the underneath side of the valve

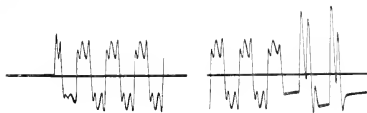

FIG. 24.

a large diameter tube be introduced so that the water column in it has a periodic time of its own and is able to oscillate similarly to the condenser circuit shunting the arc, oscillations will be set up in this column, and if the periodic time of the liquid in this column be altered, the period of the oscillations will be altered; this can easily be done by connecting air vessels of different capacity to the open end of the tube, so altering the controlling force acting on the water, in other words altering the capacity of the circuit shunting the arc.

With this water model a great many of the properties of arcs both intermittent and oscillating can easily be shown. The one point of difficulty in constructing the model is to obtain a force acting on the valve which decreases rapidly when the valve lifts and which occasions no friction. So far the only successful method I have found is to hang from the underneath side of the valve a piece of soft iron which nearly touches the pole of a small electromagnet. This gives a force which without any friction rapidly decreases as the valve lifts and works very well.

Intermittent discharges may take place either with alternating or continuous current, and give rise to oscillations as follows:—If the generator has a very drooping characteristic, or if L_0 (Fig. 23) is a very high resistance or inductance, then the condenser will take an appreciable time to charge up to the discharge voltage. After the discharge, which may be oscillatory, has taken place a

certain time must elapse before the condenser is again charged to a sufficient voltage, so that a regular succession of charges and discharges will take place even with a continuous-current supply. The time to charge the condenser depends for a fixed generator voltage and length of gap on the capacity of the condenser and on the impedance of L , including that of the generator. If the impedance is not too large the successive discharges may follow one another very rapidly. It is possible with a continuous-current supply at very high voltages, and spark-gaps that are well cooled, to make the sparks follow one another tens of thousands of times per second. Probably these intermittent discharges play a considerable part in the production of pressure rises.

The practical applications of the above short résumé of the production of oscillations by arcs and sparks must now be considered. The only capacities available are the capacities of the connections, the network, the feeders, and the windings of the machines to frame. The self-inductions available are those of the windings of the trans-

former, of 2,000 to 5,100 at the last spark before the final break.

When switching off an inductive circuit a high pressure may occur should the current be interrupted suddenly. This well-known effect in the case of continuous-current circuits can also take place on alternating-current circuits when using oil-break switches, though it is usually supposed not to be the case. It is true that the oil-break switch in general does tend to open the circuit when the current is in the neighbourhood of the zero value, but this is not always the case. Fig. 25 shows the switching on and off from a 2,500-volt sine-wave machine of a large transformer on open circuit. The oscillograph in this case was connected between the terminals of the switch so as to show the pressure rise at the switch, which amounted at the moment of switching off to 11,000 volts. The rise in pressure lasted about $\frac{1}{10}$ th of a period, that is to say about $\frac{1}{50}$ th of a second. It is to be noted that the switch only opened the magnetizing current of the transformer. When making this experiment there was a small

FIG. 25.

FIG. 26.

FIG. 27.

formers and machines and of the connections, network, and feeders.

Sparks and arcs may in practice be formed at switch contacts or when faults take place. Under normal working conditions sparks mainly take place at the switch contacts, but when large currents are being broken regular arcing is observed at the contacts. In the case of a fault, except a sparking fault to earth with both poles insulated, the discharge at once takes the form of an arc. I have already mentioned that in switching on and off cables on open circuit, pressure rises may be produced should the switch contacts chatter in going in or out. A similar effect can easily be produced by sparks between switch contacts if they are held stationary and almost touching on sufficiently high-voltage alternating circuits. For in this case at the peak of each half-wave a spark will take place tending to charge the cable first in one direction and then in the opposite. These reversals are naturally attended with the pressure rise already referred to under "vibrating contacts." Fig. 24 is a good example of the rises that may be produced when a feeder on open circuit is disconnected, intentionally allowing the switch to spark in air between its brass contacts. The voltage has risen from the R.M.S.

piece of cable between the switch and the transformer, and there is no doubt in my mind that the capacity of this cable materially assisted the suppression of the current at the spark, and consequently increased the pressure rise.

I have already mentioned that if an inductive circuit carrying a continuous current be interrupted by a switch, a condenser shunting the terminals of the switch will stop the arcing at the switch contacts and produce a serious pressure rise. The following tests show that a similar effect occurs with alternating currents. A transformer of about 150-kw. capacity was switched on and off by means of an oil switch from the 2,500-volt mains. The measurements were made between the terminals of the transformer. The connections between the switch and the transformer were very short. In this case after switching off a number of times very few pressure rises were observed. The worst is shown in Fig. 26, where there is a peak of 5,500 volts.

On introducing a length of about 60 yards of cable between the switch and the transformer nearly 60 per cent of the breaks produced pressure rises, the worst of which is shown in Fig. 27, the maximum value being 7,500 volts. These two tests illustrate very well the effect of capacity

shunting the switch contacts in increasing the tendency to pressure rises when switching off inductive circuits. It may be said that introducing a cable between the switch and the primary of the transformer does not constitute a condenser shunting the switch contacts, but a little consideration will show that the capacity of this cable to earth is in series with the capacity to earth of the supply main, and that these two condensers in series do shunt the switch contact; this is the usual arrangement whenever the switch has connected to both terminals a length of cable which has any appreciable capacity to earth.

The arcs which take place when fuses blow have similar properties, and as in this case they are nearly always shunted by the capacity of the cables connected to them, similar rises take place. Fig. 28 shows a short-circuit on the end of a feeder connected to a 2,000-volt 400-kw. generator which was allowed to remove itself by means of a fuse.

The big initial rush of current and the pressure rise attendant on the blowing of the fuse are clearly shown, the

tus situated at the end of the lead might be subjected to considerable strain, and might run the risk of having its end turns damaged owing to the high-frequency oscillations set up along the lead.

At high voltages any sparking taking place between one point of an insulated circuit and earth will set up oscillations in the leads, connections, and apparatus. The whole circuit may be considered as equivalent to a complicated aerial system of a wireless transmitter which is excited in the manner generally spoken of as plain aerial, that is, with a spark between it and earth. The effect of this is to set up a number of high-frequency oscillations in the system, producing high potentials at all points where reflections of the oscillations may take place, such as open ends and the connections to apparatus having appreciable self-induction. Berg has investigated a number of cases and has shown how a spark fault to earth may produce very high voltages localized on the end coils of transformers, etc.

Turning next to arcs, I have not yet come across a well-

FIG. 28.

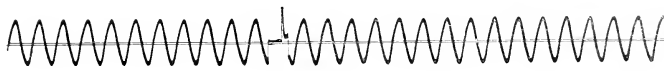

FIG. 29.

maximum value being 4,200 volts. Another example is shown in Fig. 29, in which a light fuse was suddenly connected as a short-circuit to the secondary of a 10,000-volt transformer; the fuse blew instantly. During the short-circuit the potential difference between the terminals of the secondary of the transformer was of course reduced to zero. This lasted for about half a period, when the fuse melted and a rise in pressure of 27,000 volts was recorded. In this case the great suddenness of the interruption of the current was in part due to the fineness of the fuse used, leaving very little volatilized metal to form an arc, and partly to the capacity of the leads connecting it to the transformer. A fine series of records of switching at high pressures, and the attendant rises are given by Faccioli which confirm the above remarks.

Sparking at switch contacts may also set up oscillations along the leads in much the same way as the oscillations are set up in wireless aeriels by sparking into them at their bases. The mere sparking into the lead will not in general set up very violent oscillations because these oscillations will have to pass round the generator, but should there be considerable capacity between the generator and the switch contact oscillations may be set up which will pass through the condenser to earth. In this case the appara-

authenticated case in practice of an arc acting as a musical arc and producing dangerous pressure rises. It is easy enough to produce them in the laboratory, but the conditions in practice do not seem suitable for maintaining continuous oscillations. I am of the opinion that there is a great deal more risk in intermittent arcs maintaining oscillations than from the arc producing continuous oscillations.

The opening of large currents, whether it be by switches or fuses or by faults which burn out, is always attended by the risk that the current may be suppressed too suddenly and that the energy stored in the self-induction of the circuit may not be dissipated. In this connection I am inclined to think that sufficient attention has not been paid to the self-induction of the leads and cables. Although the self-induction per mile of the cables is comparatively small—it may apparently range from a fraction of a millihenry for cables very close together to some 5 millihenries for conductors like track rails on continuous-current railways—yet the amount of energy that may be stored is considerable owing to the large currents that may flow at the moment of short-circuits or faults. It is to be noted that as the great part of the magnetic field is situated in air, should the current be suddenly suppressed the whole

of the energy is liberated at once, giving rise to very high voltages. This is not necessarily the case in machines and apparatus, as with these quite a considerable part of the self-induction may be due to the lines of force threading the iron, and it is impossible for these to collapse so suddenly on to the conductors owing to the eddy currents they would produce in the mass of material; therefore when they do collapse some of the energy is wasted by this means and the pressure rise is reduced.

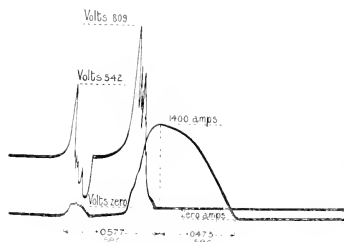

FIG. 30.

The exact values of the self-induction and capacity of the cables used for carrying continuous currents do not seem to have received much attention. Approximate calculations can, however, be made. As an example, the self-induction of one mile of two 0.5 sq. in. cables laid in non-metallic ducts at 4-in. centres is about 1.6 millihenries, the capacity about 0.1 microfarad, and the resistance 0.276 ohm. Taking these figures the maximum possible voltage rise neglecting the self-induction of the machine is 252 times the current suppressed, if the cable is considered to be equivalent to localized condensers and a self-induction arranged as in Fig. 21. For 500 amperes interrupted, the limit of the pressure rise might thus be 126,000 volts.

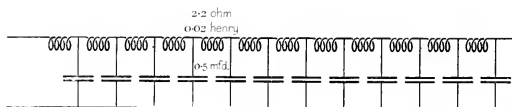

FIG. 31.

If a short-circuit is suddenly interrupted somewhere in a long cable a high-voltage wave front starts from it and travels in each direction towards the ends of the cable, where it may be reflected if the end is open or connected to a high self-induction, its amplitude being then doubled.

There is no doubt that in many cases of short-circuit—whether of a continuous current or of an alternating current—the current is very suddenly suppressed. The arc is quenched somehow, to use a wireless term. It is easy enough to quench arcs with small current, but with medium currents, say a few 100 amperes, the arc appears

to be more stable and a large amount of vapour is produced from the electrodes, yet the appearances seem to be that in the case of still larger currents the arc goes out with great suddenness. In ordinary cases of supply mains there may be two causes which tend to this quenching of large-current arcs. First and foremost, the considerable magnetic field produced by the current itself. Second, and this applies to insulated mains in enclosed spaces, the production of a gas surrounding the arc due to volatilization, and the splitting up of the insulating material. Third, the cooling effect of the large masses of the metal which are usually present in circuits intended to carry large currents. Whatever the true explanation may be, it seems to me that the properties of large current arcs, both continuous and alternating, require further investigation, especially as regards quenching. Some tests made by Collis show very well the pressure rises that may occur on breaking continuous-current circuits. Fig. 30, taken from his paper, relates to a magnetic-field blow-out circuit-breaker operating on a dead short-circuit. The voltage rose to 809, and the steady value after the circuit-breaker had operated was 226. The arc in this case appears to have been suddenly extinguished, producing the high-pressure rise, and then to have re-started, causing a second but smaller rise.

In order to illustrate the pressure rises that may occur in cables due to short-circuits, I have prepared a model line, somewhat similar to that used by Wagner and consisting of a number of sections, which has a total self-induction of 0.24 henry and a total capacity of 6 mfd. to earth distributed along it. The resistance is 27 ohms. This line may be looked upon as representing 10 or 15 miles of cable, in which the self-induction, capacity, and resistance per mile are, roughly, increased tenfold. Consequently the frequency of the line is reduced tenfold. With this line connected to the ordinary continuous-current mains it is possible to make short-circuits anywhere along it and to observe on the oscillograph the attendant pressure rises. These can be quite easily made to repeat themselves, and the wave forms can be projected on the screen. The tests made with this line indicate how easy it is to obtain very

considerable pressure rises by means of short-circuits which are suddenly opened, and they also indicate the strain at the end of the line due to the reflection at that point of the wave that travels along it each time a short-circuit is removed somewhere along the line.

I have attempted to summarize as briefly as possible the causes of pressure rises. They are numerous. Very small changes in the conditions will sometimes make all the difference between considerable pressure rises and none of importance. Pressure rises are illusive to investigate; time after time one will repeat the test without

hitting the exact condition, and then perhaps at last, after a number of trials without having made any apparent change, a considerable rise will be observed. No faith can be put in observations of pressure rises unless they are repeated many times. Tests repeated once or twice are not conclusive evidence if a rise is not observed. The importance of these rises to electrical engineers is well recognized. The means to prevent them occurring, and the precautions to be taken to try and relieve the insulation from the strain when they do occur, are matters which would take me too far for this address to-night.

NEWCASTLE LOCAL SECTION: CHAIRMAN'S ADDRESS.

By C. VERNIER, Member.

(Address delivered 20th October, 1913.)

ABSTRACT.

Previous to the year 1900, public electricity supplies in this country were, generally speaking, chiefly utilized for lighting. As the result of an investigation in 1898 a Joint Committee of the House of Lords and the House of Commons made certain recommendations, which resulted two years later in the granting of statutory powers to several undertakings formed for the purpose of supplying electrical energy over very large districts, covering in many cases some hundreds of square miles.

The advantages which have been claimed for these undertakings, and which are no longer open to question, may be briefly summarized as follows:—

- (1) The low capital cost per kilowatt of generating stations and the increased economy in running charges obtained by the use of very large generating units.
- (2) The development of high load and diversity factors, resulting from the varied uses which are made of the electrical energy supplied.
- (3) Low fuel costs obtained by the favourable location of generating stations and the opportunities afforded for the utilization of waste heat and other forms of waste fuel.

The important influence of low capital cost upon the cost of producing electrical energy was clearly brought out in a paper contributed to this Institution by Messrs. Merz and McLellan in 1904.¹ Since that time much closer attention has been given generally to the reduction of the capital cost per kilowatt of power stations, and in view of the steadily increasing price of coal it is a matter which must continue to receive great attention. Of even greater importance is the development of a high load factor and high diversity factor, both of which effect a reduction of the capital charges per unit by enabling the same plant capacity to deal with a greater annual output. The maximum economy in coal consumption can only be attained by the use of large generating sets, which further lend themselves to the lowest capital cost of installation, while on the other hand where fuel is cheaply obtained, as for instance in the case of waste heat or gas, the installation of smaller units at a higher capital cost per kilowatt may be quite justified. In general, the higher the price of fuel, or the poorer the load factor, the less can a high capital cost be defended on economical grounds. It may also be stated that in a large scheme the cheaper the fuel the more desirable it is to run the plant at a high load factor; therefore, any stations operating with cheap fuel, such as cheap coal, waste heat, or water power, must be run as nearly as possible continuously at 100 per cent load factor, the ordinary coal-fired stations dealing only with the fluctua-

tions of load. This is where the producer of waste heat finds it to his advantage to co-operate with a power company. Without this co-operation it is scarcely possible for a power station installed by such a producer to utilize the whole of the waste heat available at all times of the day and night, or in other words, to run the station as far as fuel permits on a 100 per cent load factor, and thus to obtain, as the power company can do, the best possible results.

If we now examine the conditions under which electrical energy is produced in this country, it is clear that with a few exceptions we are very far from according with the conditions that I have described as essential to a low cost of production. The multiplicity of small generating stations, some 40 per cent of which are of a capacity under 1,000 kw., supplying small districts, inevitably results in high capital charges, poor load factors, and high fuel and running costs. We, who are familiar with the extraordinary developments that have taken place in the production and utilization of electricity on the North-East Coast during the past 10 or 12 years, will be under no misapprehension as to the disadvantage under which the greater part of the country continues to be placed by this subdivision of the means of production and distribution.

When we note that the use of electricity from public supply sources in that portion of the North-East Coast served by the power companies has increased by over 3,200 per cent within the past 10 years,² and that as the result of a cheap and abundant supply of electrical energy new industries are springing up in our midst, it is surely a matter for regret that similar rapid progress has not taken place to the same extent elsewhere.

Dr. Ferranti, in his inspiring address to this Institution three years ago,³ set before us an ideal of what electricity supply should be, and it is perhaps pertinent to ask ourselves what we in this country are doing towards the realization of that ideal. Do we not see each year existing generating stations of small and moderate size being extended? Generating stations which in many cases are quite unfitted by their unfavourable situation to achieve the economical production of electrical energy. Then what of our load factors? How very few (less than 3 per cent) of our electrical undertakings of to-day can exceed even a 25 per cent load factor. Again, how many of our undertakings can profitably avail themselves of the utilization of such waste heat as may exist in their neighbourhood? Although in this district we certainly have a large share, yet we have no monopoly of waste heat and waste gases from coke ovens and blast

¹ In that portion of the North-East Coast not served by the power companies, which includes many of the large towns, the corresponding increase is under 150 per cent, which is also about the average for the whole country for the same period.

² *Journal I.E.E.*, vol. 48, p. 6, 1911.

³ *Journal I.E.E.*, vol. 33, p. 676, 1912.

furnaces; in fact, the waste heat from these sources in existence in this country would if fully utilized be more than sufficient to operate the whole of our existing public electric supply stations, with a combined maximum load last year of between 700,000 kw. and 800,000 kw.

The first step towards the realization of Dr. Ferranti's ideal must inevitably be in the direction of the centralization of all coal-fired generating plants into large power stations supplying in bulk over very large districts, so as to obtain the benefit of large outputs and increased load and diversity factors. These stations will have as far as possible to be interconnected together, while all available sources of waste fuel must be fully utilized. What, then, is the chief obstacle to the centralization of our electric power supply? Is it not largely the opposition which is almost invariably offered by municipal authorities, and particularly by the more important of them, to the exercise of private enterprise within their borders? It will not be easily forgotten how strenuously the Power Bills were opposed by the municipal authorities, with the result that in most cases the larger towns and industrial centres were entirely excluded from the area of supply, while the supply in bulk within the area of any existing undertakings is usually made subject to their consent. To this fact, coupled to the aversion of many of our local authorities to enter into contractual relations with public companies for bulk supplies, must be attributed the slow progress which many of the power schemes have achieved.

Of course it may be argued that the centralization of power supply is not of necessity a matter to be undertaken by private enterprise, in fact the Electric Lighting Act of 1909 affords facilities for the combination of a number of local authorities, but the jealousy of control between neighbouring authorities appears to be an even greater obstacle than those previously mentioned, and, so far as I am aware, there is but one solitary instance of such a joint scheme between municipal undertakings in the history of electricity supply in this country, viz. that of the Stalybridge, Hyde, Mossley and Dukinfield Joint Board, which was formed as long ago as 1901. Be it further noted that while the Electric Lighting Acts afford to local authorities the right of combination or to promote joint schemes, similar schemes between a number of companies or between local authorities and companies are denied, and even the supply from a single generating station of two or more districts scheduled under separate provisional orders but operated by a single company cannot be carried out without special Parliamentary authority; all powers granted to companies, if we except power companies, being subservient to the right of purchase of company undertakings by the local authority for the district.

Although from time to time we have been assured that the position of our electric supply industry was in no way behind that of other parts of the world, I question very much whether we can make the same statement to-day, in view of the rapid progress which is taking place in other countries at the present time. For our part, and I speak in a general sense of the whole electrical supply industry of this country, the progress of the past 10 years is surely nothing to boast of, in view of what might under more favourable conditions have been achieved. If we assume that our electric supply industry commenced in 1800—although a few undertakings were started earlier than

this—at the end of the first 13 years the annual consumption had risen to 247 million units in round figures, while in the next 10 years (1903-13) this consumption amounted to 1,318 million units, or an increase of 433 per cent. If the pioneering work of the first-named period is considered, few, I think, and least of all in this district, will be prepared to agree that the increase within the last 10 years represents the rate of progress which we ought to expect. The reason for this is clearly that the great majority of our undertakings by their operations on the restricted scale created by their condition of municipal isolation are not in a position to supply the larger users such as railways and industrial power consumers of all kinds. Nor is it possible that we shall ever be in such a position, so long as for sentimental or other reasons it is considered essential to retain a power station for each town or district, irrespective of its size or facilities for economical production. It is not surprising that under these circumstances an examination of the tables published by the *Electrical Times* shows that out of 287 undertakings whose generating costs are analysed (July, 1913) only five, or less than 2 per cent, have a works cost of 0.5d. per unit or under. Therefore, although it may sound like reiteration, we must first divest ourselves of this "one town one or more power stations" idea before we can hope to make any rapid progress.

That many of our undertakings are experiencing the pressing necessity for larger outputs and higher load and diversity factors is evidenced by the special efforts which are being made to develop electric cooking. To those of our undertakings especially whose operations are circumscribed by limitations of the area of supply, this development must be of a particular importance, and it is so far fortunate that their inability or unwillingness to improve their position by other possible means has compelled them to break new ground and direct their attention to the energetic development of this business. Meanwhile, unlike the small power business, which in many places has reached no unsatisfactory proportions, the development of the heavy industrial power supply over a large part of the country appears to be languishing, and yet how much remains to be done may be seen from the last Census of Production, which gives the total horse-power of engines in use at that date (1907) in the factories and mines of this country as 10½ million, of which 1½ million horse-power, or only some 14.3 per cent, represented the total plant capacity of public electric supply undertakings. More recent complete figures are not available, but some measure of the increase of horse-power available in our generating stations can be obtained from Garcke's "Manual of Electrical Undertakings," which shows an increase of plant capacity between 1907 and 1913 of just over one-half million horse-power for those public supply undertakings which furnished returns, or rather less than the average rate of increase since 1890. I have been unable to obtain any figures bearing upon the total horse-power of engines in use in the country at the present time, but assuming for the purpose of comparison that no alteration in the figures has taken place elsewhere than in our public electric supply stations, our progress would be represented by an increase during the past five years of 4 per cent of the total. A further surprising fact shown by the last Census of Production is that there was approximately 1,000,000 h.p.

in private hands utilized for generating electrical energy, which produced an output equal to fully 62 per cent of the entire output of our public electric supply undertakings. Comment would be superfluous.

The most important development of the not very distant future will undoubtedly be the electrification of our railways. This branch of work, if we except the London tube railways, has not progressed as rapidly as we should wish, and many reasons have been advanced in explanation of this, of which perhaps the most important is the heavy capital cost of carrying out the conversion. This will, however, become of less importance as traffic further increases and as the alternative of carrying out heavy construction works becomes more and more pressing in the future. Steam locomotives have about reached the maximum dimensions allowed by the present load gauge, and the demand is still for heavier loads and more frequent traffic—two problems which electric traction is eminently fitted to solve.

Now as to the supply of electrical energy to work our railways. Are we going to repeat the mistakes of the past, and add to our already too numerous generating stations by compelling our railway companies to put down their own generating stations, as several have done already? This load, at any rate, is not one which for various reasons our municipalities can ever hope to touch, and there is, I think, no better illustration of the shortcomings of the present state of our electric supply industry having regard to its ability to meet all demands. It is certain that the ability to supply a likely demand will largely create such a demand, and if we wish to see a more rapid development of the electrification of our railways, the electric supply industry must place itself in a position to supply all the requirements of our railway companies at a rate which will induce these companies to undertake electrical working. It is not to be supposed that our railway companies would expend the necessary capital for putting down generating stations of their own if a sufficient, cheap, and, above all, a reliable supply were to be obtained from public supply sources, a fact which is already well recognized both in America and on the Continent, not to mention Tyneside.

It appears to me that here lies the key to the future position of our electric supply industry. There would seem to be but two alternatives once the electrification of our railways begins in earnest; either, as I have said, our public supply undertakings must then be in a position to undertake the supply of all the requirements of our railway companies, or our railway companies will themselves put down large generating stations, and, as a certain stage of their electrification developments, will inevitably seek to supply other undertakings in bulk. In either case the compelling agency will be that of larger outputs and the better load and diversity factors to be obtained by co-operation. The balance of advantage should obviously lie with us, who are first in the field, and who ought, but for the reasons which I have endeavoured to set out, to be in a position to supply a railway company's demand better and more cheaply than it could supply itself, having regard to all the economies rendered possible by a joint load. There is, further, a vast and practically virgin field in the supply of electrical energy for electrochemical and electrothermal processes, which, however, will only be secured

at rates which are but a small fraction of the present works costs of the large majority of our undertakings. In this field, so far, a few of the power companies stand practically alone, and chiefly those operating in this district, where, as a result of the electrical facilities offered, a number of important new industries have erected works adjacent to the power stations of these companies.

If our position is now relatively unsatisfactory when compared not only with other leading countries, but especially, and I think this is the more correct view to take, with what it should be considering our industrial supremacy and the density of our population, it is surely a matter of the first importance that the causes which at present hamper the progress of the industry should be inquired into, and that the best means to remove these disabilities should be once more discussed and formulated in the light of present-day experience. This is a question, it seems to me, which the Institution cannot afford to ignore.

It will be of interest to observe that public electricity supply in Germany has developed on very similar lines to that of this country, in so far as many of the local authorities established their own works. Perhaps in one respect their condition was even worse than ours, for in 1909 it was estimated that 80 per cent of these municipal works were of a capacity under 500 kw. Germany is at present wrestling with this problem of the centralization of power generation, which we ourselves must eventually face, and is putting down large stations for a supply in bulk, many of them in connection with iron and coal companies, utilizing waste heat from coke ovens and unsaleable qualities of fuel. The co-operation of municipal authorities is being secured in some cases by buying out municipal undertakings upon terms advantageous to both sides, but more usually by giving these municipalities a financial interest in the power company. As an instance, the municipality of Strasburg takes the whole of its supply from a power company, in which it owns a large number of shares. This company supplies also some 70 communes in Alsace-Lorraine. As the result of the operations in 1909, the municipality received dividends and a share in the profits amounting approximately to £38,000, which, after deducting 4 per cent interest on its invested capital, left a balance of over £21,000 for the relief of local taxation. In other instances, groups of urban and rural authorities co-operating with a power company have the option of subscribing for ordinary shares in the promoting company, usually up to 40 or 50 per cent of the total capital, or in some cases, when wishing to avoid risk, to preferential shares with a fixed dividend and a further share in the profits. In each case the municipalities are directly represented on the board. The mutual advantages are obvious, in that the companies enjoy the benefit of the greater facilities afforded for raising capital, while the community through its directors maintains a live interest and a share in the control of the undertaking. Such schemes of harmonious co-operation it must be admitted cannot fail to hasten the solution of this problem.

* The density of our population in England is twice that of Germany, 3½ times that of France, and 2½ times that of the United States. This has an important bearing on the cost of transmission and distributing electrical energy, and is all in favour of the centralization of supply in the more densely populated countries, yet the more sparsely populated country is that one which has so far gone furthest in this direction, and vice versa.

It is perhaps in the United States of America, however, that the centralization of electric power production and distribution is making the greatest progress, and it is also remarkable that in that country the supply of electrical energy is chiefly in the hands of private enterprise. We have nothing to compare with the electric service in Chicago, with its maximum load of 230,000 kw. (compared with 20,000 kw. 10 years ago), or with more urban supplies such as the Public Service Corporation of Northern Illinois, which supplies 46,000 consumers in 150 communities, whose combined population is only one-half million, distributed over a tract 150 miles long, and has a load factor approaching 70 per cent. This load factor in itself is a striking example of what can be achieved by supplying various demands over very large areas. Another example, out of many which may be quoted, is the Central Illinois Public Service Company in the same State, which is gathering into one management and system the electrical requirements of a rural district of 350 miles radius (larger than the United Kingdom) with a population of only a quarter of a million, whose present 90 local generating stations will shortly be replaced by a small group of modern central stations.

The principle of State regulation of public utility services, which not only include electricity supply, but also gas, water, telephones, telegraphs, tramways, light railways, and railway services, is that which finds its adoption in the United States under the description of Public Utility Commissions. These Commissions, which are of recent origin and adoptive for each State, are appointed to deal with all questions relating to public services, such as the ratification of franchises, the settlement of disputes between undertakers, the revision of rates, amalgamations into joint schemes, the approval of new issues of share capital, technical regulation, and inspection, and not only to regulate but to press forward the development of such services. What the effect of these Commissions may be upon the intimate development of the electric supply industry in the States cannot yet be judged, but I have looked in vain for any serious criticism by those most nearly concerned of the principle there adopted, while the remarkable strides which are taking place in the consolidation of central-station interests at the present time tend to show that their effect is on the whole beneficial.* It would seem, however, as if the municipal question obtrudes itself even here, as a few of the acts specially exclude municipally owned public utilities from the regulation of these Commissions, while there is further a "Home Rule" question; large cities, for instance, Chicago, seeking, so far without success, to establish their own Commissions in place of being merged in the more usual State Commissions.

The use of overhead wires in this country has always proved a matter of some difficulty, and some of the complaints which have been made from time to time have been as follows: The objection of the Board of Trade to the use of overhead wires; the difficulty of obtaining wayleaves across country, and the absence of legislative assistance in this matter; and the arbitrary powers granted to local authorities. With reference to the first of these

complaints, whatever may have been its attitude at one time, there is no doubt that for a number of years the Board of Trade, thanks largely to their electrical adviser, has facilitated the use of overhead wires in every possible way, with due regard to public safety. This must ever be our first consideration, and I do not think there are many of us who would wish to see erected in this country examples of overhead work, for instance, of the type common in large towns in America. But without going to such extremes in cheapness of overhead construction as is frequently met with there, there is yet a substantial saving in first cost, even with the very best construction, by the use of overhead wires in place of underground cables. The higher the voltage the greater the possible saving becomes; while at pressures exceeding 30,000 to 40,000 volts three-core cables for three-phase transmission can no longer be used, except perhaps in short lengths. It is only necessary to add that the power companies in this district have already 170 miles of overhead transmission lines, mainly operated at 20,000 volts, as evidence of the facilities which have been enjoyed for a number of years.

The difficulty and delays in obtaining wayleaves is a serious obstacle in the development of overhead construction, and our position in this respect compares very unfavourably with that of other countries, notably Italy and Switzerland, which have adopted legislation compelling the grant of wayleaves for overhead lines across private lands. Such works are there viewed as of public utility, and private interests are not allowed, subject to compensation, to take precedence of the general interests of the community. However much we may feel that similar legislation would benefit the electric supply industry, we have but to examine the privileges conferred by Parliament upon our Post Office—a State department with unusually wide powers. These are contained in Section 2 of the Telegraph Act, 1892, and Section 4 of the Telegraph Act, 1908.

While some attempt has been made to recognize the principles of public utility to which I have referred, the powers granted are in such a form as to render them of little or no practical service; in fact I am not aware that they have ever been exercised. We unfortunately cannot hope to obtain greater powers than the Post Office, which has a Cabinet Minister to look after its interests, and, further, such a different view is here taken of the rights appropriate to the ownership of land than is common in more democratic countries, that I am not at all sanguine of our being able to secure greater facilities from Parliament possibly within our generation.

It follows that the use of overhead wires for transmission purposes is at present to a large extent at the mercy of our landowners, but we in the north are fortunate in the fact that the land is largely in the hands of large owners, whose interests are so intimately bound up with the industries whose needs we seek to supply, or, if not, who are already so well accustomed to wayleave matters in connection with the mining industry, that, apart from delays, we do not experience the same difficulties as are perhaps strongly felt in some other parts of the country. The slow progress of negotiations is, however, a serious, but in the circumstances an inevitable, objection, which we must at present accept with the best grace possible.

The Electric Lighting Acts have probably done more to discourage overhead wires than all the rest put together by

* A leading New York banker has recently stated in an address that the electrical industry in the States can profitably employ a capital of £80,000,000 per annum for the next five years.

stipulating that before any overhead wires are erected the consent of the local authority must be obtained. It will probably come as a surprise to some present this evening to learn that this stipulation not only applies to the erection of overhead wires in public streets, but to all overhead wires, even if erected entirely on private land. It is difficult to understand what could have been in the minds of the framers of these measures, when we contrast the position of non-statutory undertakers with statutory companies. The former, of course, are not at all bound by the Electric Lighting Acts, with the exception of one single clause, to which I shall refer shortly. Thus an individual or company which does not work under an Act or Provisional Order can erect overhead wires on private land without the consent of the local authority. Further, such an individual or company, in the absence of special local by-laws, of which very few are in existence, can erect overhead wires across public roads without seeking any consent from the local authority, provided the consent of the owners of the soil on each side of the road is obtained, and also that the wires are erected at such a height above the roadway that no obstruction is caused. Lastly, non-statutory undertakers are not compelled to erect their works in the first instance in compliance with any regulations of the Board of Trade, except that under Section 4 of the Electric Lighting Act, 1888, it is provided that the Board of Trade may, if it thinks fit, serve a notice upon the owners of such overhead lines requiring that they continue to be used only in accordance with such regulations as the Board may prescribe. As the Section of the Act referred to was obviously intended to bring under the control of the Board of Trade all overhead lines erected by non-statutory owners previous to the passing of this Act, it is somewhat extraordinary that the serving of a notice upon the Board of Trade before the erection of further lines was not made compulsory under the Acts. Non-statutory owners, such as iron and steel manufacturers, collieries, and others, have therefore a roving commission to erect overhead wires on private land and, with few exceptions, across public roads without seeking the consent of either the local authority or the Board of Trade. In my opinion it is essential that an early opportunity should be taken to amend the Electric Lighting Acts in this respect, for if, as all agree, regulations are essential in the case of statutory undertakers, how much more are they necessary in the case of non-statutory bodies, who are usually the least qualified by reason of their not being primarily engaged in electrical work, and whose interest in the matter is frequently limited to considerations of the lowest tender.

Efforts should also be made to secure a curtailment of the absolute veto of the local authorities in regard to overhead wires, particularly if it be not proposed to erect these wires along public thoroughfares, and the local authorities' consent should in all cases be made subject to an appeal to the Board of Trade. At present such an appeal is only allowed in the single case of power companies' wires in rural districts, but in the case of all other companies' overhead wires, or with power companies in the case of overhead wires in urban districts and boroughs, there is no appeal whatever from the decision of the local authority, which is thus entitled to refuse its consent, or to attach unreasonable conditions thereto, without any further means of redress being available to these companies.

I would not have it thought that I am in any sense advocating a general use of overhead wires in place of underground cables. Both have their uses, and I think the more legitimate use of overhead wires in this country in the future will be for transmission lines across private land and at very much higher pressures than are used at present. A further consideration in the use of higher transmission pressures in this country is the practical impossibility, for many and various reasons, of erecting an entirely continuous overhead system, and most of our overhead lines must of necessity include a fair percentage of underground cables over sections of the route; therefore, whatever pressure may be adopted for the overhead system must also be suitable for use with underground cables. This leads to an examination of the high-voltage cable position. No very notable advance can be recorded since the laying of the extensive 20,000-volt three-phase cable system in this district some seven years ago, if we except a large system of 30,000-volt three-phase cables laid in Berlin about two years ago, following upon the experience obtained here. There are, I understand, some short lengths of 45,000-volt three-core three-phase cables in use in France, but, as far as I know, this is the highest pressure hitherto applied to three-core cables in commercial service, and it is difficult to foresee any possibility of exceeding this or even much lower pressures on a large scale on account of the heavy capacity currents and increased dielectric losses (which, it must not be overlooked, are continuous losses and independent of the load) which would be experienced at our usual frequencies. While with cables these losses increase in proportion to the square of the voltage, they are practically non-existent on overhead lines up to the limit of pressure at which corona effects take place. Another factor which largely determines the highest pressure that can economically be dealt with by an underground three-core cable is the maximum diameter and weight of cable which can be handled. Beyond this, it is necessary to resort to the use of three single-core cables at a greatly increased cost. At present I would set down the superior practical limit of pressure for three-core cables at not more than 40,000 volts, while there is no very obvious difficulty in constructing single-core lead-sheathed cables for three-phase work up to a working pressure of 50,000 volts per cable—that is, over 80,000 volts between phases with the neutral point earthed. Capacity currents and the copper and dielectric losses to which they give rise, and also sheath losses arising from the use of single-core cables, would not prove of such serious importance if these cables were used as an adjunct to our overhead lines in moderate lengths, distributed as usual at points along the route. I therefore apprehend no serious difficulty in increasing our overhead line pressures to anything between 60,000 and 80,000 volts if required.

Considering the importance of the subject, our knowledge of the science of cable design is still very incomplete, and although the general principles are fairly well established there is a remarkable dearth of technical data upon the properties of extra-high-tension cables. It is evident, for instance, that our thicknesses of insulation for extra-high-tension cables are in many cases unduly liberal and purely arbitrary. From what we know of potential gradients it is clear that a thickness of insulation

which will be correct for a large size of core, as, for instance, 0.25 sq. in., will not necessarily be correct for a smaller core, or for a round core against a clover-leaf core. The potential stresses will be relatively much greater in each of the last-mentioned cases, and yet we find that our engineering standards do not discriminate between such cases, but even allow thicker insulation on the larger sizes of cables compared with the smaller. It is no wonder that many of our paper cables frequently show factors of safety of 10, or even more, under test, and we might well refer to such as factors of ignorance. One cannot commend our lack of enterprise in research. While our cables undoubtedly rank as the best in the world, this position has been arrived at more as a result of careful attention to details of manufacture than by the application of scientific principles to design. Although there are happily signs of an awakened interest in this matter, still there appears hitherto to have been no co-ordinated efforts to place it upon a sure foundation, and yet I feel confident that a full investigation should enable a reduction to be made in our thicknesses of insulation, with a consequent saving of possibly anything from 10 to 25 per cent in the cost of extra-high-tension cables (6,000-volt and upwards) as the result of smaller overall diameters and the consequent cheapening of lead sheaths and armouring. This question is one for further investigation, but in the meantime we may take some comfort from the prospect that many of our existing cable systems are capable of being worked satisfactorily at much higher pressures than those for which they were originally laid down.

We may look to see some interesting developments in the utilization of waste gases within the next few years, both for the production of electricity and for town gas lighting. Use is already being made of coke-oven gas for town lighting in Germany and America, and, to come nearer home the town of Middlesbrough has just entered into a contract with a firm of ironmasters to take the whole of their town gas supply from coke ovens; while another interesting experiment is that of the Birmingham Corporation, who have installed some coke ovens primarily to produce town gas and to dispose of the furnace coke produced as a by-product. Seeing that coke-oven gas should be obtainable at some figure below 6d. per 1,000 cubic feet, keen competition may be anticipated in those districts where such gas is available. The utilization of waste heat to its fullest extent for electrical purposes is only possible to those power companies with widely ramified networks, as much of it is only available at a distance from the large centres of population and chief points of power utilization; but by feeding into the main network at so many points remotely situated from the chief power stations considerable economies in the transmission system and its losses may be

attained. Of course there are objections in the way of its rapid adoption, such as the limited quantities of waste heat usually available at any one plant, which would result in heavy capital cost for small stations; but when the use of by-product recovery ovens becomes more general it will doubtless in some cases be possible to concentrate the generating plant, the gas being piped from a number of near by-coking plants to a power station placed at some point favourably situated with respect to these sources of production. Another, and perhaps at first sight more serious, objection is the liability to interruptions from labour troubles and industrial depression, resulting in the shutting down of the producing plants. Some alternative method of keeping the station plants in operation, such as coal or oil firing, or producer or oil gas if gas engines are used, would be desirable at some of these stations, but not necessarily at all. This might in these cases be necessary to maintain the general scheme of distribution in the transmission system, although loads would obviously be very much diminished in such circumstances.

I do not think I need pursue these and other technical aspects of the problem of the centralization of power supply any further. The hindrances to our progress are by no means technical in character, and it is true that the world's achievements in electrical and mechanical engineering are far in advance of any of the possible requirements of this country for many years to come. When we learn, as from the States, of 30,000-kw. turbo-generators, of which seven are already under construction, the daily operation of high-voltage overhead transmission up to 140,000 volts and covering distances up to 240 miles, of 300,000-h.p. central-station developments and the electrification of some hundreds of miles of main-line railway, we need have no fear as to the ability of engineers to keep pace with the world's industrial demands. But for ourselves can we ever hope to maintain our position in the electrical engineering world if we are content to allow our electric supply industry to develop along its narrow way; indeed, have we not already lost too much ground? What training ground shall we offer the rising generation of British electrical engineers if we wish to take our part in the electrical development of our Empire overseas, and how shall our electrical manufacturers assume their proper place in the markets of the world when handicapped at home by a restricted market, which might easily be increased to many times its present proportions? Truly this question is more far-reaching than may appear at first sight. It is not my intention to discuss here the seemingly delicate question of how one may best reconcile the different and admittedly powerful interests which at present operate to the disadvantage of our industry, and I shall esteem my task well done if I but succeed in turning your thoughts in this direction.

WESTERN LOCAL SECTION: CHAIRMAN'S ADDRESS.

By H. FARADAY PROCTOR, Member.

(Address delivered 27th October, 1913.)

The Western Local Section has completed the first year of its existence, and it may be justly claimed that the result has been not only satisfactory, but that it has exceeded the expectations of the promoters. Last session four ordinary meetings were held for the reading or discussion of papers, etc., and the average attendance was 50; a result very creditable when due regard is given to the distances to be travelled by members attending our meetings.

In addition to the formal discussion of electrical matters, we have—by the kindness of their proprietors and managers—been able to pay visits to works of interest, and social intercourse has been promoted by the arrangements made for meeting together at dinner after completion of the business meetings.

Although much has been done in a short space of time to bring together the members of the Local Section and to promote further friendly relationship, the objects of the Section cannot be considered to have been fully achieved until we read and discuss at our meetings selections of the Papers approved by the Papers Committee for general reading and discussion before the Institution and the Local Sections. It must be borne in mind that the object of a Local Section is not confined to the welfare of its members; it is formed with the view of enabling its members to do that which may be of use to the Institution as a whole, and the electrical industry generally.

It is desirable, therefore, that papers read and discussed at the Local Sections should not be of local interest alone, but whatever their source they should as far as possible appeal to the greater body of members and be read and discussed before the Institution in London and at the various Local Sections.

The Committee have decided that for the present the holding of dinners after the ordinary meetings is to be discontinued. I regret this decision, as I feel that great good is likely to result, and has indeed already resulted, from such informal gatherings, because of the educational benefit which perhaps results more often from the smoke-room conversation than from the lecture-theatre conference; also because of that all-important factor, the promotion of good fellowship. In another association with which I am connected, viz. the Incorporated Municipal Electrical Association, it has been very fully realized that the backbone of the Association has been the friendly relationship that has been established between all grades of members and the large body of visitors who are attracted to the meetings, formal and otherwise. The marked superiority from this point of view of the gatherings in provincial towns over those held in London, resulting from the enforced intercourse at hours both late and early, is generally recognized and highly appreciated.

Advice is so often sought as to the proper course of training for an electrical engineer, that I may perhaps be

pardoned for introducing a few comments upon that somewhat well-worn subject. I would suggest that it is desirable that the boy be first a gentleman; secondly, make him into a man; and thirdly, into an engineer. If he lacks the instincts of a gentleman he will not gain confidence; if he has not learned to behave like a man he will progress but slowly on his own initiative, and will require constant pushing; whilst if he has not the elementary principles of engineering ingrained, he will not get on even when pushed, and he will be for ever searching for complex solutions of simple problems and giving attention to details when broad principles are at stake.

I think it has been very generally admitted that the study of mechanical engineering is an essential preliminary to becoming an electrical engineer. Mechanical engineering is the broad foundation upon which electrical engineering is based. I fear, however, it is too often forgotten that mechanical engineering must itself have a foundation broad in proportion to the superstructure to be erected upon it, and capable of unlimited expansion in every direction. The young engineer does not know in what particular direction he may have to develop, and a broad intelligence based upon a sound general education is the best asset of an engineer, when combined with resourcefulness and an anxiety to understand and give due regard to all matters which pertain to the subject under consideration, although such may not strictly belong thereto.

The foregoing remarks perhaps apply more particularly to the student or young engineer rather than to my audience, who have already passed these stages and have made their way in the world.

Although I generally prefer English methods to those of our American cousins, among the many things we can learn from across the water is to keep well in mind the American definition of an engineer, viz. "a man who can do for one dollar that which any fool can do for two." The higher a man ascends the ladder the less time he has to devote to technicalities, and it is only by close attention to the commercial or financial side of business that men can hope to rise.

Although such is the more fascinating branch of our work, we, as business men, must to a considerable extent attend our Institution meetings and follow the work of the Institution with a view to its helping us in our business, and we must not look to the Institution merely as an interesting hobby.

Our Institution should, in my opinion, act as the advisers of all Government Departments in relation to matters of principle affecting the electrical industry, and should, where necessary, act as the arbitrators where differences arise between different branches of such industry.

Two subjects to which our Institution (through its Council and Committees) has recently been giving very close attention are Standardization and Co-operation.

I look upon standardization as the key to cheapness (without nastiness), and co-operation as the key to standardization.

A great work has been undertaken by the Engineering Standards Committee, and great good has already resulted. I look forward with much pleasure to the time when the standardization of two-pin plugs and sockets, heavy current lamp-holders, and fuse terminals, will remove the most common source of the consumers' everyday little worries.

To promote our own efficiency, we should carry standardization throughout our office work. I believe few can realize the economy of time and freedom from worry that would result from anything approaching perfect method in office working. How few there are who can compile an efficient index to all the matters with which they have to deal in their daily business, and work to such an index. How few can file information on a proper system, and turn up the necessary item at the moment it is wanted.

The standardization of paper sizes would greatly facilitate such filing. Efforts have been made in this direction, and a little has been done—much more, however, might be done. For example, if our manufacturers would agree as to the size of paper to be used for their catalogues and correspondence a large amount of chaos on our bookshelves would be reduced to order, and by co-operation between the various societies the bulk of communications between engineers might be reduced to standard sizes, thereby very greatly facilitating reference. The compilation of a standard subject index carried to the necessary degree of finality, would also prove of great utility. The need for standardization, with the resultant economy, becomes the more urgent in electricity supply departments owing to the decreasing revenue derivable from the individual "lighting" consumers.

When the one-watt lamp came to the fore there was doubt in the minds of many as to its probable effect upon the sale of electricity. As another change similar in character—although less in extent—is about to be introduced, a few figures relating to the result of the former change may be of interest.

In 1909 a careful comparison was made of the consumption of electricity by a large number of consumers in Bristol who had installed one-watt lamps throughout their premises, with that of the same consumers when using carbon-filament lamps. Care was taken to ascertain that the results were directly comparable. The result (averaged) showed an economy to the consumer of 53·8 per cent. Since, however, the one-watt lamp represents an economy of about 68·5 per cent., it is evident that those consumers had on the average increased the candle-power installed by about 50 per cent. It is further interesting to note that after a lapse of four years the proportionate figures still hold good. From this it would appear that the average consumer has been educated up to require illumination 50 per cent in excess of that with which he was satisfied before the introduction of one-watt lamps.

With the advent of the "half-watt" lamp, I believe a similar result will be obtained. We may expect to see these lamps in use within the next month or two, but like their immediate predecessors they will not in the first instance be constructed of small candle-power for the pressures most usually found on supply mains.

Increased intensity of illumination will not be necessary,

but lighting by electricity will, with the half-watt lamp, cost so small a sum that business premises will be more generously lighted, and in residences artistic effect will be given greater consideration, whilst less attention will be paid or necessitated as regards economy.

Since the light given by the half-watt lamp is very much whiter than that of the one-watt lamp, it should be excellent for the judging of colours. The lamps should, however, be kept well out of the direct line of vision, and indirect lighting should thus be encouraged to the utmost extent.

The "cost of electric light"—if I may be pardoned for using such an expression for the sake of brevity—will be so reduced as to put all competitive forms of illumination out of court; and the fact that electricity will henceforth be adopted for lighting all premises requiring artificial illumination (even if only for the sake of economy) will tend to keep the cable system satisfactorily loaded.

With the diminished revenue per consumer, the cost of making new connections will become a still more serious factor in the cost of supply. In Bristol the present cost of connecting premises adjoining the mains is £3·8s. (exclusive of the cost of the meter). Since the average revenue per connection derived from as many as 20 per cent of the lighting consumers amounts to only 35s. per annum, the importance of this item is evident. It is also obvious that the uses of electricity for purposes other than lighting must be developed to their utmost; otherwise the lighting consumer may become a serious drag upon the undertakings.

Another matter of serious import, which the lighting engineer should bear well in mind, is the probable adoption of a Daylight Saving Bill. The advantages to the general public resulting from such a measure appear to me to outweigh so far the disadvantages, that I cannot realize why the suppliers of artificial illumination have been allowed up to the present to enjoy their existing load factor.

Electric cooking has developed wonderfully during the last year or two, and with the standardization of details will rapidly displace its rivals.

I believe that the satisfactory heating of water for domestic uses will soon remove what is now the greatest obstacle advanced against the introduction of electric cooking. To get rapid and highly efficient water heating, it will, I consider, be necessary to use immersion heaters, probably applying the heating element direct to the water, and avoiding the risk or possibility of shock by utilizing the resistance of two columns of water—one on the supply side and the other on the delivery side of the heating appliance, the supply and delivery extremities of these columns of water most remote from the heating elements being electrically short-circuited and earthed. The elements must in such an appliance be either self-cleaning or arranged so that they may be very readily cleaned in order to avoid trouble due to lime or other deposits. For the probable solution of the domestic hot-water problem I look to such appliances arranged alternatively for rapid water heating, the energy being supplied at the usual heating tariff, and for continuous use at a fixed annual kilowatt charge.

Several years ago it was prophesied that we should have to look to the development of the use of electricity for

power purposes for our revenue. That prophecy has been very amply proved. For example, in this city the power consumption has increased 8 times as rapidly as the lighting consumption during the last 10 years. During the next two years this ratio will be doubled.

I have endeavoured to condense my remarks as much as possible, and have merely drawn attention to the urgent necessity of expanding the uses and demand for electrical

energy, also of co-operation and standardization in order to secure such expansion by furthering economy and efficiency, and finally of so training the electrical engineer that he will be resourceful himself and inspire confidence in others; for it is to the "business getting" department that we must look for the bulk of our progress. We must bear in mind that an article is more easily made, than sold at a profit.

MANCHESTER LOCAL SECTION : CHAIRMAN'S ADDRESS.

THE VOCATION OF AN ELECTRICAL ENGINEER.

By PROFESSOR E. W. MARCHANT, D.Sc., Member.

(Address delivered 4th November, 1913.)

The proper education and training of an engineer have been discussed at such length and so frequently within recent years that I feel a certain reluctance in taking for the subject of my address this evening one which bears, or might appear to bear, any direct relation with that question. It seems to me, however, that the time has come when it might be advantageous to look round at the vocation of the electrical engineer to see what he has accomplished and to make an attempt to determine the place that he should fill in the industrial world, the steps which may appear possible to improve his status, and the reward that he should receive for the long and arduous training through which he has to pass before he can be regarded as a fully qualified member of his profession.

My chief reason for discussing this subject is that the electrical engineer to-day is a very specialized person. Electrical engineering has developed so rapidly and in so many directions that it is now impossible for one man to keep in touch with what is happening in all the branches of activity in which electrical engineers are employed. Each man becomes obsessed, and very rightly so, with the work for which he is responsible; he busies himself in becoming acquainted with the technical development of his subject, and there is, I think, some danger that the "human" aspect of his profession may become forgotten and may be neglected.

In dealing with this subject it is my intention to discuss the possibilities and prospects of electrical engineering for the individual engineer, and not so much the development of electrical engineering (that has been dealt with already by abler hands than mine); and though the two subjects are necessarily intimately related, there are certain aspects of what I may call the "human" side of the question which I think deserve special consideration.

It is also opportune at this time to discuss the subject, because the Institution has recently organized a system of examinations to test the quality of the candidates who wish to join its membership. In putting this scheme into operation it is following the example that has already been set by the Institution of Civil Engineers; and, in passing, may I express the hope that some of the things that have come about in connection with those examinations may not creep into the examination scheme of our Institution. I refer

particularly to the risk of people cramming for the examination in order to get through, without going through a course of training and getting a real knowledge of the subject of which the examination is intended to provide a test. The examination scheme has been drawn up (with the same intention, I presume, as all examination schemes have been devised) to test the knowledge of the candidate, and to avoid, as far as may be possible, the prospective member cramming for it. Those who have had experience of this work know how difficult it is to achieve this end, especially after the examination has been in operation some time, and it is the hope of a good many of those engaged in educational work that besides showing ability to pass an examination the prospective candidate should also give evidence of having passed through a recognized course of instruction in some approved institution.

The examination is a step in the direction of attempting to provide that members of the Institution shall really understand the principles underlying the work in which they are engaged, that their work should not be done merely by rule of thumb, and that evidence should be given of the capacity to think. To produce men of this kind is the object of all the universities and technical colleges of higher grade. That this has not been recognized more generally is possibly to some extent the fault of the institutions concerned, but it is to be hoped that the result of the establishment of the new examination scheme may lead to a closer connection between the Institution and the chief training colleges—a result which should prove of much ultimate advantage to both.

The electrical engineer, like every other member of the civilized community, has to take a place in the social structure; his position must depend (and here I do not mean his position in any narrow sense) on his recognition of the position his labours take in the work of the world. On the recognition of this fact by the world at large depends his future, not only from the point of view of influence, but also financially, and it is from this standpoint that I wish this evening to take a brief survey of his position.

I propose in the first place to discuss the prospects and opportunities which seem to me likely to occur in the various branches of work in which electrical engineers are engaged at the present time. The discussion is not in-

tended to be exhaustive. It will be impossible to find time to touch upon many branches of work in which members of this Institution are actively employed, but I hope that what I say may draw some attention to this most important aspect of the life of an electrical engineer.

CENTRAL-STATION ENGINEERS.

The construction and supervision of stations for the supply of electric power must always provide occupation for a considerable proportion of electrical engineers. The running of a small station, *i.e.* the mere keeping of the engines and dynamos in order, is work which requires a comparatively small amount of general knowledge of electrical engineering principles. In America the running of such stations is largely in the hands of men who have had no thorough training in the principles of their profession; in some cases they are really "engine drivers" in the narrow sense. Central-station engineers in England have been trained very differently, and I believe the result has been most beneficial to the development of electrical power supply.

The ideal central-station engineer is one who must possess a great variety of qualities; not only must he be a good engineer, but also a good man of business. In the opinion of many the latter qualification is the more important; but it is mere platitude to say that if this qualification is not combined with a sound knowledge of engineering principles, if the engineer is not able to keep in touch with all the most recent developments, his station will soon get out of date.

The central-station engineer is destined in the future to take a still more important place in the life of the community than he occupies at present. The use of electrical energy for lighting and domestic purposes has progressed, some think, too slowly, but it is significant that no one who has ever experienced the advantages which a supply of electrical energy gives, ever wishes to go back to any other system. Without looking to any of the more startling developments to which Dr. Ferranti has done so much to draw attention, there is an enormous field for the central-station engineer.

The remuneration offered, however, to those taking up this work is quite inadequate to its responsibility. Besides direct evidence, which must be known to all, I should like to draw attention to one or two facts which bear on this point and which are of importance. It is a matter of common knowledge that successful central-station engineers, in all but the largest cities, have in many cases forsaken their positions to take up consulting work, and are retained by their former employers as consulting engineers. It would surely be better worth the while of most central-station authorities to have at the head of affairs men of experience who would be able to do all the necessary work for the central station without outside advisers being called in. If this is to happen, it must be made worth the while of the central-station engineer. It is significant also that the salary offered to those who wish to enter some of the power companies has increased to a most marked extent during the last year or two, due to the fact that the supply of men has rapidly fallen off. I heard the other day of a case in the West of England where an engineer who years ago had dozens of men on his books who were

anxious to get into central-station work, now has none. The list of vacant positions in the electrical journal advertisements is more than twice as long as that of men wanting employment. This is a very healthy sign and is a hopeful augury for those who have started in this profession.

If the office of electrical engineer to a town or city is to become one of increasing honour and importance, it is essential that it should be filled by thoroughly trained men. I do not wish here to lay great stress on college education, although that in the view of educationists is an essential element in the training of such people; but they should be persons of good general knowledge and high intelligence, in order that, when the time comes, they should be competent to assume the greater responsibilities which will rest upon them. To attract such men it is essential that these positions should be made financially remunerative. One cannot expect a man of promise to be content to spend ten years of his life preparing for a profession which in the end will yield no adequate return for his expenditure of time and money. We have heard a good deal lately of the poor payment of members of the medical profession. A panel doctor with 1,200 patients receives a fixed income of at least £360 a year, and this may be regarded as a minimum salary for a qualified medical practitioner to-day. The training through which an electrical engineer engaged in central-station work now has to pass, with three years at college and three or more years at work, is as exacting as that which a doctor receives. Yet there is a very large proportion of central-station engineers in this country, and I am not speaking here of people in positions of great responsibility, who would be glad to regard the above as their minimum salary. The electrical engineer of a town can do as much (if not more) for the health of the community as any other person in it; he can brighten the homes of the people, make them hygienically better places to live in, he can supply the power to enable them to cook their food, and in combination with the gas engineer he can get rid of nearly all the smoke and dirt which hitherto have made large towns such objectionable places to live in. Surely such a man, whose work affects the life of the whole community, deserves as ample a recompense as the man who treats a limited fraction of its members.

ELECTRIC RAILWAYS.

The electrification of railways seems likely to be the direction in which the most important developments will take place during the next few years. The railway companies to-day are in a better position financially than they have been for some years, and the competition of tramways and motor-omnibuses makes it imperative that the electrification of suburban lines should be carried out if the railways are to retain their local traffic.

The results obtained by the Lancashire and Yorkshire Railway, the London, Brighton and South Coast Railway, and by the Metropolitan District Railway, are outstanding examples of what electrification can achieve. The electrical engineer who intends to go in for railway work has apparently a great opportunity. The risk, from the standpoint of the electrical engineer, is that the railway man will regard the railway side of the problem as the fundamental one, and the use of electricity as a side issue. In a way this is true, and it behoves the electrical engineer

who looks on this work as his future vocation to recognize the fact and to equip himself with a thorough knowledge of railway conditions.

Take two obvious examples: The arrangement of a schedule of trains for a suburban line is a problem of some mathematical complexity; the estimation of the power taken by an electric locomotive on a given line of road entails a large amount of detailed calculation and a thorough knowledge of mechanical principles.

For this class of work the necessity for a good general engineering training is evident; but, given this essential training, the field of the electrical engineer in railway work becomes very wide—he must concern himself with the erection and maintenance of central stations and substations for the supply of electrical energy, he has to design and maintain a complete system of feeders and overhead conductors, and finally, he has to design and supervise the running of the electrical equipment of the trains. But the electrical engineer is not responsible solely for the supply of motive power, for in a modern system in cold or tropical climates provision must be made for the heating or cooling of the trains, as well as for providing a supply of electric light. As electric railways progress it seems certain that the position of mechanical engineer to a railway will be filled by an electrical engineer, and if the success that has attended the promotion of an engineer to the position of general manager of a railway has the effect one may reasonably anticipate, the electrical engineer may regard as a legitimate aspiration that he should be called on to fill this great administrative position.

MANUFACTURING.

The greater number of men with whom the staffs of universities and technical colleges have to deal find their way to the manufacturing firms, and a considerable proportion of the membership of the Institution is engaged in the design and manufacture of electrical machinery and apparatus. The equipment of the engineer intending to take a responsible position with a large firm has to be, from the technical standpoint, more complete and thorough than that required in any other branch of electrical engineering. If the practice that has been followed in Germany, and to a certain extent in America, is to come into operation here, the manufacturing firms will supply consulting engineers who will advise as to the character of the plant that is to be used in connection with any large scheme of power supply. Such positions involve great responsibility, and require technical knowledge of the highest order to fill them adequately; men of wide experience both in manufacturing and in constructional engineering are necessary. Let us consider now what likelihood there is, under present conditions, of such men becoming available.

It is easy enough for men who have had a college training to enter works at the present time; most manufacturers seem only too anxious to obtain their services, and a living wage in many cases is paid from the start, but the number of openings that are better paid is much less. There is a great gulf fixed between the men who are "just" on the staff and those in leading positions in a works, and in the long interval that must elapse before one of the first class become eligible for the higher posi-

tions there is a period of great difficulty for most engineers, in which the best men feel that they are wasting their time. In some cases men have left the profession who would otherwise have proved themselves a valuable addition to it. The main point that I would urge is that this condition is a discouragement to many able men who might otherwise have entered electrical engineering and have done much to advance it.

I was discussing this matter the other day with a man in a good position with one of the best-known electrical engineering firms in the country, and he gave me as his opinion, that in his firm a man of initiative and energy might hope, by the time he had reached, say, the age of 35, to receive a salary of £300 a year; of course there are some who would receive less, and a few who would receive a good deal more, but I think all will agree that this prospect is not such as to attract into electrical engineering the bright minds and keen intelligences which it is so essential for the welfare of the industry should be attracted.

Even in the early days of an engineer's career in a works his remuneration is less than it should be. I know of one firm who offer a college-trained man who has served his apprenticeship 30s. a week to start with, whilst a mechanic who has served his time can get 50s. What is the result? The only men who go to this firm are those who want to get a practical experience and who are on the look-out for a better post from the start. The best men leave almost at once; the men who are not worth much remain.

The criticism I am making does not apply to some works; it does not apply, as far as I am able to judge, to American works, though the same difficulties arise in the works of many German firms. The manufacturers have been in a very strong position in the past, because the supply of trained men on which they could draw has been large; now the conditions are changing, and I would strongly urge that in order to attract the best type of persons into the profession of electrical engineering the standard of remuneration for technical men must be advanced. The expense involved is not large compared with that necessitated by an increase in pay of the workmen, since the number of such people engaged in manufacture is relatively small; surely it is to people of this type that a manufacturer must look far more than to any other for the progress and advance of his business, and it is of the greatest importance to him to ensure that such people shall be forthcoming in the future.

The manufacturers have been hard put to it during the past ten years. The keenness of competition and the excess of the output over the demand for electrical apparatus have not tended to make the business of electrical manufacture remunerative; under such circumstances it is useless to urge the principles which I have quoted; now, I venture to think, the conditions are changing, demand is overtaking supply, and the prospects of the manufacturer to-day, I believe, are better than they have been at any time during the last decade. I hope, therefore, that it is a suitable time at which to urge this matter, and to lay stress on the necessity of ensuring that the prospects of those entering an electrical engineering works shall be at least as good as those in any other branch of engineering practice.

TELEGRAPHY.

The branch of electrical engineering which originally gave its name to this Institution forms to-day a comparatively small part of it, though possibly the proportion of engineers interested in telephony and telegraphy is considerably larger than many of the members of this Local Section would imagine.

The operating branches of telegraphy and telephony are under the control of the Government, and those engineers engaged in what the Germans call "*Schwachstromtechnik*" possess all the advantages and disadvantages of Government service. As in other branches of the Government service the position of its engineers is not as satisfactory as it might be, and the plea which has recently been made by one of the leading electrical journals for a fuller recognition of the working branch will find an echo in the minds of all those engaged in this work. It is to be hoped that the higher administrative positions in this service will in the future be more open than they appear to be at present to those who have a thorough knowledge of the technique of telegraphy and telephony.

It is only by a complete co-ordination of the technical and administrative sides of this undertaking that the greatest economy and efficiency can be reached, if that end is to be attained the electrical engineer must be ready and fully equipped for administrative work. Here, again, it is the right type of man that is wanted. To get the right kind of person the engineering side of telegraph and telephone engineering must be made attractive enough to ensure that the most able men shall think it worth while to become telegraph engineers. In this connection it will be within the memory of all that an engineer, for whose reputation all who know his work have the highest respect, was recently prominently before the public in connection with the Marconi affair. It was a matter for comment that this man was spoken of frequently in Parliament and elsewhere as a clerk, no doubt partly for political reasons, but mainly because it was the view of the people who spoke, that a man receiving such a salary as was mentioned could not hold the position of a responsible engineer but must be in one of inferior responsibility.

The case for improved conditions in the telegraph service is overwhelming. Some of those engaged in the manufacture of telegraph and telephone material have recognized this, and offer advantages which are unequalled by any other electrical firms. The Government telegraph service now appears, however, to adopt a different policy. The importance of the service of the telegraph and telephone to the community to-day demands that those engineers engaged in its direction shall receive recognition at least equal to that given to those responsible for any of the other great national services.

ELECTROCHEMICAL ENGINEERING.

The application of electrical energy to chemical manufacture has made great strides during the last decade, and the price at which electrical energy can now be sold makes it evident that electrochemical processes will come even more extensively into use, not only for the manufacture of alkalis, carbides, and the like, but also for smelting iron and steel. The questions involved in the application of electrical energy to purposes of this kind are essentially engineering problems. The chemical and thermal pro-

cesses of most of these operations are well known, and the application of them involves the design and operation of suitable furnaces and machinery which will enable the manufacture to be carried out on a large scale. Electrical engineers should find a considerable field for their activities in this direction, and one of the advantages this branch of engineering possesses is that it is likely to be rapidly progressive as the cost of electrical energy decreases. It is to be hoped that this work will not be left in the hands of those more directly concerned with chemical problems, as progress is much more likely to be rapid if the mechanical design of the plant is sound. This fact has been illustrated already in electrical engineering of the more mechanical kind, where the application of electrical machines has undoubtedly been retarded by the faulty mechanical construction of many of the early types of dynamos and motors. The percentage of electrical engineers in the Institution interested in electrochemical engineering is very difficult to estimate; it is small at present, and is not destined to become as large as that engaged in the manufacture of electrical machinery, but there seems little doubt that there will be a rapid growth in this industry. The training for such an engineer should be a thorough engineering training, combined with a good knowledge of chemistry, a curriculum which is provided in most of the larger technical schools and colleges. It remains for the users of these processes to employ the raw material that is being produced.

CONSULTING ENGINEERS.

The consulting engineer has been consigned by some people to a speedy end, as far as electrical work is concerned, his place being taken, as has already been suggested, by engineers employed by large firms. It will, however, be a long time before the consulting engineer finds himself without occupation. Consulting engineering as a vocation can, however, hardly come within the scope of this brief survey, since a consulting engineer is necessarily a man who has had experience in one of the branches of engineering to which reference has already been made. The vocation of consulting engineer is one of great distinction, but the number of people who act as consulting engineers must always be comparatively small, and the vocation is one which must be regarded as supplementary to the branches of practical work to which I have drawn attention.

I have made some attempt to classify the membership of the Institution with a view to finding the proportion engaged in each branch of work. The classification is very incomplete, and has been applied to only one class, namely, Members. The thing that has surprised me has been the apparently large proportion of men engaged in the business of the supply of electrical power who are members of this Institution. That, of course, is the greatest work at the present time, but it is one which will not, I believe, tend to increase very rapidly as an employment for engineers. The tendency to-day is towards large power stations and long transmission lines; anyone who has seen the large power stations in Canada and the States, especially those operated by water, cannot but have been impressed by the very small number of engineers required in the case of stations of, say, 50,000 kw. capacity.

The first conclusion reached from this classification is that there must be a large number of electrical engineers engaged in manufacturing and constructional work who are not members of this body. These men are of great value to an Institution such as ours, because it is they who are really in the forefront of discovery; they know all about a new machine and a new design long before the operating engineer comes across it. I do not think the Institution can be regarded as being to blame for this, as the papers read during recent years have dealt in no small degree with subjects which should interest designers, and I hope an effort will be made to bring men of this type into the ranks, as they cannot fail to strengthen the membership.

A consideration of the opportunities which offer themselves at the present time makes it clear that the electrical engineer of the future must be able to take a broad view of his profession, whether he be engaged in central-station work, manufacture, telegraphs, railways, or as a consultant, and he must be able to see all sides of a question. He must be able to solve new problems along sound lines. If men of this kind are to be available as electrical engineers, it is essential that the best type of person must enter the profession. Much depends on this in the future. If the electrical engineer does not look to his laurels, there is a risk that the "plums" of the profession may fall into other hands; and unless employers on the other hand are prepared to offer adequate salaries, they run the risk of failing to secure the best people on their staffs. The position to-day is critical, and on the attitude of the industry to its engineers depends the future of the electrical engineer. The magnitude of the tasks that lie before him, the complexity of the problems he has to solve, the greatness of the results he can achieve, are unequalled in any other calling. For the best results the best men should be got, and whether the best men take up electrical engineering depends entirely, or almost entirely, on whether it is made worth their while to do so.

As far as one outside the industrial world can judge, the prospects of the electrical engineering industry at the present time are exceedingly good. The supply stations have recovered from the set-back which they received when the metal filament lamp was introduced, and the fact that electric light on the basis of the cost of illumination, with a supply of energy at rates such as exist in Liverpool and Manchester, is actually cheaper than lighting by gas, is becoming generally recognized.

The use of electricity for power is coming more and more rapidly into operation. The electrification of railways seems at last to be making great strides forward, and we hear of schemes from nearly all the leading railways of this country for the electrification of considerable portions of their track.

The electrification of cotton and wool mills, and the use of the electric drive for rolling mills and for factory work of all kinds are progressing apace. The only cloud on the

horizon is the motor-omnibus, and it is not unlikely that even this vehicle may become sooner or later a source of load for the power stations. Electrochemistry for manufacture is making rapid strides, while wireless telegraphy is in the air and has stimulated the cable companies to great efforts in improving communication.

The prospect for electrical engineering then is good; it is even better if one takes into account the openings that are available for those willing to go abroad. It behoves the electrical engineer, then, to make use of his opportunities and to see to it, as far as lies in his power, that there may be great difficulty in obtaining really competent and well-trained electrical engineers at too low a salary. This sentiment, no doubt, appeals to all members of this Institution, and I lay stress on it, not for the very obvious reason that we should all like to have a little more money, but because it must be acknowledged that the income derived at the present day by most electrical engineers from their profession is generally not high enough, considering the importance of the work they have to perform.

The interest and fascination of the study of electrical science have attracted into the ranks of electrical engineering many who from the point of view of making money would have taken up some other branch of work, but that fascination can only exercise an influence in the comparatively small number of cases in which the requirements of life are a matter of secondary importance. There is no profession of which it can be said that the persons in it have a greater enthusiasm for its progress and a greater faith in its ultimate triumph. Without unduly lauding our own Institution or the corresponding American Institute, I think it can be said that the general interest shown by all members in a paper of really first-rate importance is not exceeded by any other engineering institution.

This is a great asset to any industry and to any science; without such interest and such enthusiasm progress is impossible. But that is not all. It is essential to the welfare of any profession that it should attract the best type of person, the man of good training, broad mind, and wide outlook. It must be made evident, therefore, that electrical engineering offers at least as great an opportunity as any other career. This fact should be remembered by those in the higher positions who control the remuneration of junior men, and especially by employers in the large companies, which now direct so large a proportion of the manufacturing industry. If the positions of responsible electrical engineers are improved, it will be a good day not only for the firms concerned but for electrical engineering generally. The matter is one of supply and demand: the supply hitherto has been ample, the demand meagre; now, demand is overtaking supply, and the necessary consequence of an increased demand is either a worse quality of product or a higher price.

It is to be hoped that the members of this Institution who have it in their power will see that it is the latter alternative that is chosen by the electrical engineering industry.

YORKSHIRE LOCAL SECTION : CHAIRMAN'S ADDRESS.

By W. B. WOODHOUSE, Member.

(Address delivered 6th November, 1913.)

Engineering covers so wide a field that there is a natural tendency for engineers to segregate, and, in the pursuit of their own particular branch of the industry, to overlook the work done by those engaged in other branches. This has been in the past particularly true of the problems relating to the utilization of coal, and therefore a broad consideration of these problems may be of value. The consideration naturally falls in two parts : the extraction from coal of its valuable properties, and the distribution of its heat energy.

The valuable properties and constituents of coal are many ; in addition to the heat derived from its combustion there may be obtained ammonia, tar, pitch, cresote, benzol, cyanides, sulphur compounds, and other products. The value of these chemical products is enormous, and the process of burning coal in its raw state wastes them entirely. To burn raw coal is a process of the same primitive nature as that adopted by Lamb's Chinaman for the production of roast pig, and to continue the analogy, it is time that we discovered the needlessness of firing the house for the sake of the crackling.

The most inefficient use made of coal is to burn it in the domestic fireplace ; not only is some 70 to 80 per cent of the heat lost, but the pall of smoke which hangs over our towns as a consequence of the practice is actively injurious to health and agriculture.

When consumed under steam boilers and utilized to produce steam power, the case is little better ; the best modern practice accounts for only 15 per cent of the heat energy, and the average practice for not more than one-half of this.

Due primarily to the work of Sir Charles Parsons, there has been notable progress made in the utilization of steam in recent years, and if coal be regarded merely as a fuel, the present utilization is approaching the limits of possible use ; future progress must be on broader lines. The heat value of a ton of coal is some 30 million heat units. If the coal is burnt to produce electricity, there its value ends ; if it is distilled in the manner adopted by gas engineers some 20 per cent of the heat energy is made available in the gas produced, and some 60 per cent left in the resultant coke, but in addition tar, ammonia, and other valuable products are released, and the sale of these makes a substantial entry on the debit side of the balance sheets.

As an example of the value of the process of carbonization of coal as carried on by gas-works, the published figures of the costs and receipts of a large gas works are instructive. The cost of manufacture, excluding capital charges, amounts to 22'80d. per 1,000 cubic feet of gas made. The receipts consist of :—

Gas	...	25'55d.	per 1,000 cubic feet of gas
Coke	...	7'40d.	" " "
Tar	...	2'03d.	" " "
Ammonia	...	2'57d.	" " "

These figures are sufficient evidence of the value of the process adopted. While this method of utilizing coal is

greatly in advance of the practice of burning which accounts for the greater part of the coal consumed in this country, it is yet open to criticism ; the gas engineer's primary object is the production of gas, and the process of distillation adopted while giving a maximum yield of gas does not make the best possible use of the coal. A variation of the temperature of carbonization is accompanied by a variation of the quantity and illuminating properties of the gas, of the production of ammonia, and of the properties of the hydrocarbons produced ; and in view of the demands for the various coal products, it is obvious that there may be room for variation of the method of carbonization dependent on the relative values of and markets for the various products.

For example, there can be no doubt that at present the most efficient means of heating dwelling-houses is by means of a central heating apparatus replacing all the open fires, but this method is so contrary to the prejudices of the people that its adoption makes only slow progress, and in the meantime much has been heard of the advantages of burning a smokeless fuel, a semi-coke from which the chemical products, if they may be so called, have been taken away. The production of such a fuel involves carbonization at a much lower temperature than that of a gas retort, and the yield of certain products of distillation is increased.

The development of the principle of carbonization on broader lines has, however, come from the needs of the iron and steel trades, the largest users of coke. Furnace and foundry coke in the past was produced in bee-hive ovens, wastefully so far as utilizing the chemical products of the coal, and not particularly economically in producing coke.

The evolution of the by-product oven has, however, changed all this, and now in addition to producing coke for the ironmaster, the mining engineer produces gas, tar, ammonia, benzol, and other valuable substances, and so makes efficient use of the raw material, including incidentally a greater yield of coke.

The method adopted for distributing the energy of the coal will determine the particular process of carbonization to be used ; but whatever process is adopted for the extraction of the valuable products from coal, that process can only be carried on economically on a large scale, and therefore the distribution of coal energy, whether in the form of solid fuel, gas, or electricity, must be on a large scale also. In other words the essential centralization of coal-carbonizing plants implies distribution of light, heat, and power over large areas and in large quantities, and under such conditions electrical means are by far the most economical.

Up to the present time electricity has been generated in central stations by methods akin to those adopted by individual power users, only more economically due to the advantages of centralization. That is to say, a public supply is merely a co-operation of users to take advantage of certain economies.

The next step forward is a further co-operation of the electricity supply undertakings with other processes, involving the use of coal. And the first example in Yorkshire of co-operation of this kind has recently been set to work at the coke ovens of the Old Silkstone Collieries in conjunction with the Yorkshire Electric Power Company. In this case the surplus gas from the coke ovens produces continuously day and night some 2,000 kilowatts of power, which the power company supply to their customers by working the station in conjunction with their general system. Such an arrangement as this is only possible on a large scale, but its economic advantages are obvious.

The manner in which coal is used to supply the demand for light, heat, and power, is dependent very largely on the methods of distribution available. Of the various methods the most successful must be ultimately that which is cheapest and most convenient, convenience carrying with it a due regard to healthfulness.

So long as no other means of heating and cooking were available, the distribution of coal to dwelling-houses was inevitable, but with a recognition of the folly of burning coal the alternative of burning coke or smokeless fuel (semi-coke) must increase, and if no other means of distributing energy were available would eventually entirely alter the present practice.

Now regarding only convenience and cleanliness, the use of gas presents advantages over that of coke, and the use of electricity over both. Domestic labour must be reduced, the utmost cleanliness must be established, and the healthiest conditions maintained. On these three points electricity is superior as a means of distribution. But in regarding cost one must recognize that the production of coke or semi-coke will be in the future enormously increased, and unless the demand increases with production its price will fall to such a point that in many cases its cheapness will outweigh the advantages of its competitors.

Not to look too far ahead, then, one may safely conclude that a demand will exist for solid fuel in dwelling-houses, marking a transition stage from coal to electricity. In the same way dependent on the laws of supply and demand, coal gas and producer gas will find a place in the general scheme of distribution. But as gas, coke, oil, and tar can all be used as fuel for the production of electricity on scientific lines, there can be little doubt that domestic needs will be principally met by the supply of electricity.

For power purposes electricity generated in the same primitive manner adopted by the individual power user is steadily displacing all other methods, and this because in addition to its convenience it can be supplied more cheaply than power can be produced in isolated plants. That it can be so supplied is due to the advantages of centralization already mentioned, and if we add the advantages of co-operation with other processes in extracting the valuable properties from coal, the advantages become enormously increased.

In the future distribution of energy electricity must take a large and, I believe, predominating part. But its progress is not solely controlled by engineering and chemical problems such as those to which I have referred; one must also consider the legislative and financial conditions under which the supply of electricity must be developed. Technical difficulties may be overcome by individuals, but

legislative obstacles will only be removed if the electrical industry moves the public to call for it.

The first step to be taken is to encourage a better understanding between the State departments, the municipalities, the power companies, and others engaged in the business.

The legislation affecting the public supply of electricity has not been helpful in development on broad lines, and State control has generally speaking been repressive rather than helpful. The economical development of our natural resources deserves and acquires a helping hand, and the utilization of coal might well be regarded as equally worthy of State support as, say, the London Docks.

The veto of local authorities, the power of purchase granted by the Electric Lighting Acts, and the general influence of municipal trading, have not made for progress.

As a case in point, the fear in municipal minds of the effect of the competition of electricity on their gas undertakings may be instanced. Anyone familiar with the development of electric supply in this country knows that this has been one of the most potent reasons for the acquisition of electric lighting powers by local authorities, and where both gas and electricity supply are controlled by the local authority future developments may anticipate similar opposition. Broadly speaking, the local authorities are afraid of the power companies, the gas engineers of their electrical brethren, and so on all round. The time has come for this partisan spirit to be swept away and for the problem to be dealt with on broader lines altogether; unless this is done progress must lag and the country suffer.

State control should aim at assisting those engaged in the industry to obtain the best results. Municipal spirit and local pride should not deny the advantages of new developments as they arise to their ratepayers, nor a share of the benefits to those individuals who by their enterprise develop more efficient conditions. Private enterprise, while best fitted to break new ground, would yet be assisted by the financial support which could be given by the State and the municipalities.

Where municipal trading is indulged in directly, the advantages of cheap money, such as municipalities can raise on the security of the rates, are great, but the moral obligation not to speculate with such money is great also, and the natural effect of such trading is to discourage new developments which might depreciate undertakings already financed with ratepayers' money.

The best results can probably be obtained by a compromise; let private enterprise continue to develop improved methods, and if the municipalities desire to exercise some control of the developments, then let them assist in the finance.

Some years ago, in addressing this Institution, I suggested that municipalities might with advantage to all parties subscribe to debenture issues of public-utility companies. The steady effect of municipal capital would yet not act as a brake, and with their financial interest some measure of control would naturally be exercised.

In a public supply a service at the lowest rates can only be given if money is cheap; and cheap money demands adequate security. If the investor can be assured of State control of public utilities, coupled with reasonable protection, just regulations, and a measure of financial support, we need have no fears of the future progress of electricity supply in this country.

SCOTTISH LOCAL SECTION: CHAIRMAN'S ADDRESS.

By J. A. ROBERTSON, Member.

(Address delivered 11th November, 1913.)

Before commencing my address as Chairman of this Local Section I should like to refer to the ceremony which took place in this city a few weeks ago, when a statue was unveiled to the memory of Lord Kelvin on a site adjoining the University. I need scarcely remind you of Lord Kelvin's connection with our Institution. He was one of the original founders of the parent Institution, and was President no less than three times. He did this Section the honour of becoming its first Chairman, and again occupied that position in the session of 1906-7 up to within a few months of his death. The members of this Institution require no memorial to remind them of the great work that he did for us, not only by his scientific discoveries in the laws relating to magnetism and electricity, but also by inventing that long series of standard electrical instruments which perhaps have done more than anything else to make electricity the precise and accurate application of science that it is to-day. It is well, however, that the citizens of Glasgow should have erected a memorial which will constantly bring before them the association of Lord Kelvin with their city, and the great work which he accomplished, not only for electrical science, but also for navigation and in many other directions.

We are passing through a period of extremely rapid development in the multifarious applications of electricity, and questions which appeared but a few years ago to be in the domain of pure speculation are now claiming attention as practical problems waiting for solution in the near future.

The efficient utilization of the natural fuel resources of the country by concentrating the manufacture of power in large central stations and transmitting over areas extending to hundreds of square miles, the abolition of the smoke clouds which disfigure and pollute our cities and towns, the electrification of our railway system, the possibility of replacing existing systems of motor transit in our streets by cheaper, cleaner, and safer methods, the application of electricity on a large scale to chemical processes, and its employment in the production of steel and iron, these are some of the questions which will claim attention from the electrical engineer within the next few years.

I do not propose to-night to take up any of these problems in detail, and should like with your permission to discuss some recent developments which have brought these questions to the front, to indicate the existing limitations to further advancement, and to consider in what direction future progress lies.

The possibility of concentrating power generation in large central stations is primarily due to two causes:—First, the improvements made in the steam turbine during recent years; second, the development of high-tension multi-phase systems of transmission.

We have had the steam turbine with us for many years, and although recent developments have been chiefly in

what is known as the impulse type, yet it will be generally admitted that we owe to Sir Charles Parsons the credit for giving us the greatest advance in prime-movers we have ever known. The turbine is free from nearly all the limitations of the reciprocating steam engine, and combines simplicity of construction with economy of operation. Its efficiency is high compared with the steam engine and fairly uniform over a wide range of load. It requires little attention, and can make long continuous runs under severe fluctuations of load, while its overload capacity is greater than that of any other prime-mover. A modern power station equipped with water-tube boilers and steam turbines represents practically the limit of economy so far as present knowledge goes. A 5,000-kw. turbo-generator will deliver a unit of electricity at its terminals for about 13½ lb. of steam at 550° F. with 28-in. vacuum at the condenser; while a 10,000-kw. set may bring the figure down to 12½ lb. This appears to be the limit of economy in the existing state of progress, and it is possible to supply energy from central stations under these conditions at rates cheaper than any private user could generate it for himself. But the fact remains that even in the best modern power station equipped with the latest type of water-tube boilers and laid out to secure the maximum economy by the use of economizers and superheaters, and with every care taken to prevent unnecessary loss, we are only able to secure an overall thermal efficiency in the station of about 15 per cent. That is to say in converting the energy stored up in the fuel into electricity, from the time it enters the boiler fire until it is delivered at the switchboard, we lose 85 per cent in the process of conversion; 30 per cent of this loss may be attributed to the boiler-house, in the form of heat lost in the chimney, radiation from boilers and piping, and leakage in the boiler settings and flues. In the turbine 5 per cent will be absorbed by friction and radiation, 4 per cent in generator losses, while the remaining 40 per cent is rejected in the form of heat to the condenser. To improve the efficiency of the turbine we require to increase its range of temperature, and the only practical way to do so at present is by additional superheating of the steam. The difficulty in using high superheat for turbines is purely one of construction, calling for the use of special materials and improved methods of fixing and arranging the parts exposed to the higher temperatures. Bearing in mind the tremendous advance which has been made in recent years, there is good ground for believing that these difficulties will also be overcome. In the meantime they constitute the chief limitation to a higher efficiency being obtained from the steam turbine.

DIESEL ENGINE.

The high thermal efficiency of the Diesel engine, which may be taken at 30 per cent (or twice the efficiency of the

water-tube-boiler-steam-turbine combination), constitutes a strong claim for its adoption in central-station work. A further advantage is the absence of stand-by losses, and also the ability to bring an engine into use at very short notice. The chief limitation in my opinion to the use of Diesel engines on a large scale for central-station work is our dependence on foreign countries for supplies of oil fuel. It is true that the Navy and also the Mercantile Marine are adopting oil fuel either for raising steam or to burn in the engine cylinder direct, but it must be remembered that for marine purposes the use of oil fuel possesses many important advantages (such as increasing the radius of action in the case of battleships) which are of course absent in the case of central stations. We should be dependent on a price which might fluctuate within wide limits, and if as appears probable, the use of oil is extended in the Navy and also in the Mercantile Marine, there may be difficulties in meeting the demand. Having regard to these considerations, I am of opinion that British engineers will do wisely to confine themselves for central-station work to a type of plant which can be operated with coal, our natural fuel, of which we have, and are likely to have, an abundant supply for many years to come.

PRODUCER GAS ENGINES.

The producer gas engine can be operated with almost any kind of coal fuel, and has a thermal efficiency considerably better than the steam turbine, although rather less than the Diesel engine. Its efficiency may be taken at about 27 per cent, or if producer losses are included, there is a combined efficiency of about 24 per cent. Of these losses about 20 per cent will be absorbed in the cooling jacket, and about 30 per cent ejected to the exhaust pipe. If it were possible to increase the range of temperature and construct gas engines of compound or triple expansion type, a much higher efficiency could be obtained, but the mechanical difficulties in the way of making compound gas engines are enormous, and unfortunately these multiply as the size of the engine is increased. The limit at present appears to be single-stage engines of 4,000 horse-power. There is still room for improvement, and I believe the gas engine will play an important part in the central station of the future.

If we could combine the mechanical and operating advantages of the steam turbine with the thermal efficiency of the gas engine, we should have a much improved combination. The efficiency of a gas engine is highest with a steady load, but that type of engine has practically no capacity for overload. The steam turbine, on the other hand, has a high capacity for overload, and is fairly efficient at light loads. If these two types of prime-movers were combined in one generating station, it would be possible also to recover, for the purpose of raising steam in specially constructed boilers, a large proportion of the heat now rejected to the gas-engine exhaust, while the heat absorbed in the cylinder water-jackets could be utilized as feed water for the steam boiler. With a combination of this kind we could, I think, raise our station efficiency from the present figure of 15 per cent to something like 25 per cent. With such an efficiency, and with the further advantages that concentration gives in the way of lower first cost and reduction of standing charges, there is no reason why electricity could not be sold under a scheme

such as that outlined by Dr. Ferranti three years ago, at a price which would enable it to be used for every conceivable industrial and domestic purpose.

Assuming that the engineering problems were solved, there is still a serious difficulty in establishing any scheme for the generation and supply of electricity on a large scale, due to the existing interests which have been established under statutory authority. There are already between 400 and 500 supply undertakings in this country operating under Provisional Orders or special Acts, of which about three-fourths are owned and operated by local authorities.

There has been a tendency in certain quarters of late to decry the backward state of our industry, which is attributed to certain specific causes:—

First, the restrictive legislation imposed by Parliament on private companies; and

Second, that the bulk of electric supply undertakings in this country are in the hands of local authorities.

To prove this contention, statistics are sometimes given showing the relative consumption of electricity in this and in other countries on the basis of units sold per head of population. I cannot quite agree with either of these views. If our alleged backwardness were confined to electrical applications, the argument might have more weight, but as a matter of fact it extends to many other industries which are not in the least affected by legislation. Take the case of our railways. They are owned and managed by private enterprise, no restrictions by Parliament or local authorities exist to prevent them taking up and working new ideas, and yet in the matter of railway electrification, and even in such details as automatic signalling, we are relatively far behind other countries. These comparisons with America overlook the difference in conditions which exists between a country having a much larger area, with a rapidly increasing population, with new districts opening up, and with new industries being constantly introduced, and an older country like Britain densely populated, with many old-established interests, and with a natural conservatism which clings to existing ideas and systems. It must also be remembered that while in America the prices charged for electricity are comparatively high, they are relatively more favourable to electricity than the prices charged in this country, where we have to compete against the cheapest gas in the world.

The charge made against municipalities of obstructing electrical progress is also, I think, somewhat unfair. Nothing can be said on behalf of a municipality which follows a pure policy of obstruction; but cases of that kind are, I believe, the exception rather than the rule. On the other hand, it can safely be said that our municipal electric supply undertakings, especially those in large cities and industrial towns, have shown results which will compare very favourably with the results obtained by private companies. In the case of smaller municipalities it should not be overlooked that many of them embarked in the business of supplying electrical energy at a time when bulk supplies were not available, and they have survived through a period when the conditions were not nearly so favourable as they are to-day. They are all under obligations regarding repayment of capital from which private companies are exempt, and on the whole have shown good financial results with

moderate charges for supply. They have educated the public to the use of electricity and have provided much valuable experience. In the light of our present knowledge it would appear that most of these smaller generating stations will ultimately be superseded by a bulk supply from another authority; but having regard to the conditions under which they were started and have been operated, it is hardly fair now to charge them with obstruction for continuing to operate undertakings which have hitherto met all local requirements. It would also be unfair to permit a power company to enter these areas and pick out the larger power users at competitive prices, leaving the local authority to supply the lighting and small power users only.

We have to face the position that these undertakings are already in operation, and the problem of cheap supply for all purposes will not be solved by purchasing a municipal station here or supplying in bulk elsewhere. The question is too big to be dealt with by isolated arrangement, and while co-operation between the various local authorities themselves and between local authorities and power companies may require to be entered into as a temporary expedient, the ultimate solution must come from a scheme dealt with on broad national lines; such a scheme is at least as important as the telephone service, and would justify the appointment by the Government of a commission of experts to investigate the whole question and report fully with special regard to such problems as suitable generating centres, the economic radius of supply, the standardization of voltages and periodicities, and the purchase of existing interests.

TRANSMISSION.

For transmission of energy high-tension multi-phase current has become standard practice, and in view of the adaptability and efficiency of this system for all conditions it is hardly likely to be superseded. The use of multi-phase low-pressure current for power purposes is also on the increase, and in the light of present experience it may be questioned whether central-station engineers in this country have acted wisely in adopting wholesale a 3-wire transmission system which temporarily increased the economical radius of supply but has since proved to be only a stop-gap between the low pressure 2-wire continuous or single-phase current and the present system of high-tension transmission. Reliability of supply and absence of breakdown, either to our mains or to the wiring on consumers' premises, are of primary importance, and from this point of view the simplest and most reliable system is undoubtedly a 2-wire system of distribution with high-tension transmission to sub-stations. The undertaking with which I am associated employs 3-wire distribution, partly from the generating station and partly from sub-stations, but in an extension to a neighbouring town now being carried out we propose to use a 2-wire distribution system throughout for power and lighting. In this case we had to deal with a number of consumers with demands ranging from 200 kw. up to 800 kw., some of them having private installations operated at pressures from 200 to 250 volts. The position of these consumers enabled them to be grouped together on two sub-stations with short lengths of feeders, and on going into the matter I decided to adopt the pressure of 250 volts on a 2-wire system for both kinds

of supply. The additional expense involved, compared with a 3-wire system for the same area, is not more than 25 per cent in this particular case, and I am of opinion that the saving effected in balancers and switchgear and the benefit of interchangeability between the power and lighting systems, combined with the simplicity and safety, will fully compensate for the extra cost.

STORAGE BATTERIES.

Recent developments in the manufacture and use of storage batteries are claiming considerable attention. When central stations were first built, storage batteries were installed to equalize the load or to maintain the supply during week-ends to enable the steam plant to be shut down. As the stations grew larger they outgrew the capacity of the battery, and in many cases batteries were discarded or retained simply for load-levelling and balancing.

In electric traction systems the battery has been more generally used, and has been of considerable assistance in dealing with rapid fluctuations of load. Quite recently the question of batteries has come into prominence again, and in one large municipal station a battery capable of discharging at 3,000 kw. on a one-hour rating has been installed. This is still a long way behind the sizes of batteries employed in lighting stations in America, where it is not unusual to keep a battery capacity sufficient to take the whole of the station load for short periods. The New York Edison Company have a battery of 11,000 kw.-hour capacity on a one-hour rating, but which is capable of discharging at 25,000 kw. for short periods. The use of such batteries is twofold. They can be employed to deal with sudden demands and also for the daily peak loads, and for this purpose they may be compared with an equal capacity of generating plant. Their more important function, however, is to take up the load automatically in the event of a breakdown of any unit of the generating plant. From this point of view I think a large battery is justified. It is becoming increasingly important to secure reliability of supply, and the annual charges on the battery may be looked on as a form of insurance against breakdown. The security and stability which a battery gives to the station under these conditions are certainly worth paying for. With a multi-phase system of transmission the proper place for storage batteries is of course in the sub-stations, where they can be used as a stand-by, as load-levellers, and also enable the high-tension plant to be closed down at times of light load for testing or repair.

The chief limitation of the storage battery is the use of lead for electrodes and acid for the electrolyte. Much has been done to improve it both mechanically and chemically, but many of the original defects still remain. These are the great weight in proportion to capacity, insufficient mechanical strength, rapid deterioration of electrodes, and inability to withstand heavy charges or discharges without injury. The duration of the lead-plate central-station battery is not more than 7 or 8 years, and to obtain even this life a battery requires very careful attention.

ELECTRIC AUTOMOBILES.

In America much attention has been given to the storage battery for automobile purposes, and many of the defects of the lead battery appear to have been successfully overcome. The greatest advance is undoubtedly the battery

invented and perfected by Mr. Edison after 8 years' experimenting. In this battery the lead plates are substituted by electrodes of steel and nickel, and an alkaline electrolyte is employed instead of an acid. It is said to combine comparative lightness with great capacity, and mechanical strength is attained without any reduction in efficiency. It can be discharged at almost any rate up to the short-circuiting rate without apparent injury, and although it is advisable to charge at normal rates, it is possible to give the cells short "boosting" charges of half an hour's duration at five times the normal charging rate. The use of an alkaline electrolyte overcomes many minor troubles, such as the corrosion of terminals which is experienced with acid batteries, and the mechanical arrangement of the electrodes and terminals is a great advance on former practice. At present it is somewhat expensive compared with the lead battery, and its use at first will be chiefly for automobile purposes. The makers claim that when used on a taxi-cab service doing an average duty of 50 miles per day the battery will propel the car 150,000 miles—practically a 10 years' life—without requiring renewals or mechanical repairs, and they are prepared to enter into a guarantee that after 4 years' use under all possible conditions of automobile service the car will retain its original capacity. If these claims are substantiated, it appears that we are at the beginning of a new development of automobile work which is bound to have a far-reaching effect on the electrical industry.

We have had practically no experience of electric automobiles in this country beyond one or two half-hearted attempts which were made some years ago to run an electric omnibus and cab service in London. On the other hand, there are in the United States over 20,000 electric automobiles in daily use, and over 40 firms engaged in their manufacture. The capital invested in the industry is £12,000,000, and the energy used for charging is estimated at 65 million units per annum. What opportunity is there for the electric automobile in this country? Compared with the petrol car, the advantages of the electric vehicle are its simplicity of construction, freedom from repair, easy and noiseless running, and better control. With electricity at 1d. per unit the electric vehicle compares under present conditions very favourably for economy with petrol cars. As the batteries can be charged at times convenient for the power station, the load is one which most station engineers would be glad to supply at 3d. or even ½d. per unit.

The limitation of the electric car is of course its restricted radius of travel on a single charge. Even if charging stations were established over the country this would still constitute a disadvantage to those who desire quick travelling over long distances. There is still an enormous field, however, for the electric car in cities and towns, where its advantages over the petrol car will be specially appreciated.

The commercial car offers still greater possibilities for the use of secondary batteries. In this case the disadvantage of limited radius and moderate speed do not apply. The commercial car as a rule travels from 25 to 35 miles a day, and returns to the same garage at night. Wear and tear of petrol engines on these heavy cars is a considerable item, and it is considered necessary to allow depreciation on the basis of a five years' life. As an

instance of what is being done with commercial electric cars, I might state that when in Paris on the occasion of the visit of this Institution last May I took the opportunity to call at the municipal department which is responsible for the collection of the city's refuse and its transmission to the destructors, where I had the privilege of examining and testing some 5-ton electrically-propelled refuse wagons, one or two of which had been in experimental use for nearly two years. The battery, which was of the lead-plate type, specially manufactured for the purpose by a French firm, was contained in boxes in a fore-carriage, and the motors, of which there were two, each rated at 7½ h.p., were mounted under the carriage and geared to the front axle. The equipment was arranged for 4 forward speeds and 1 reverse speed, with electric braking on the regenerative system. These operations were all performed by a single handle connected through gearing to a tramway-type controller. The steel body was divided into five compartments, and coupled to the fore-carriage in such a way that it could be detached by unhooking two screw-bolts, and replaced, when required, by a street-sweeping machine or watering-cart. Anybody who has driven a heavy commercial car of the petrol type could not help being impressed with the superiority of the electric car for this class of traffic, and it was not surprising to learn that the Paris municipality, after making tests extending over two years with both types, had decided to adopt the electric. An order had been placed for 100 wagons, the idea being gradually to replace the whole of the horse-drawn vehicles used by this department. Several other towns on the Continent have decided to adopt the electric car for municipal purposes.

There is undoubtedly a great field in this business awaiting electrical engineers in this country, and if properly introduced and organized it should mean a large addition of trade for manufacturers of batteries and motors, while incidentally providing a desirable load for central stations. It is to be hoped that when this new business is introduced to this country we shall avoid the blunders which we have made with nearly every electrical development up to the present, and go in for a complete system of co-operation and standardization from the beginning. It will be absolutely necessary to standardize the charging voltage of batteries, and the capacity for each particular size and type should also be kept as nearly uniform as possible. There is no reason why the motors and control gear should not also be made in standard sizes, so that replacements of any part could be supplied from stock with the minimum of cost and inconvenience to the users.

To attain success there must be thorough co-operation between the manufacturers and the supply engineers, and the question is one of sufficient importance, I think, to claim the consideration of a committee of this Institution representing the various interests involved. If these interests work together on proper lines there is no reason why the electric automobile business should not be at least as successful here as it has been in the United States.

HEATING AND COOKING.

Generally speaking, the outlook for the electrical industry was never more hopeful than it is at present. Electric lighting has passed out of the region of controversy, while

the electric motor is fast superseding all other forms of power application. Another branch which has developed rapidly of late is electric heating and cooking. As regards heating, we have now numerous designs and types of radiators and convectors to meet all conditions. The convenience and cleanliness of electric heating constitute its unique advantages, and its limitation at present is purely financial.

With regard to electric cooking the position is still more favourable. Owing to the great efficiency of electric cooking devices as compared with either coal or gas appliances, a sound case can be made out for electric cooking from the point of view of economy, in addition to its other advantages. The only exception at present is the difficulty of furnishing an adequate supply of hot water for all household purposes. In the meantime the best arrangement seems to be a combination of electric cooking with a water heater fired by anthracite or coke. From personal experience I can say that this arrangement is thoroughly satisfactory and economical.

The design and construction of cooking apparatus has advanced enormously during the last two years, but there is still room for improvement. There is a difficulty at present in obtaining a heating element which is cheap, mechanically strong, and which will work continuously in household use for more than 2 or 3 years at a temperature corresponding to red heat. Many firms are now engaged on this problem and I have not the slightest doubt that it will be successfully overcome in the near future. An important point to remember in connection

with electric cooking is that of safety in handling the appliances. Electrical cooking appliances in the kitchen should at least be as safe as apparatus in a factory which has to conform to Home Office Regulations.

We occasionally hear criticism of the low prices at which electricity is sold for heating and cooking as compared with the rates charged for lighting. There are sound reasons why electricity can be sold for these purposes at so low a rate as 0.5d. per unit, even in those cases where the cost of production may be substantially greater.

It would be out of place to discuss these reasons here, but I would only point out that it may be perfectly sound policy for a trader to introduce a new article to the market at a price below its actual cost if by so doing he can attract a volume of business sufficient to reduce the cost of production to a figure which will yield a profit and at the same time recoup him for his preliminary losses.

Electricity is an ideal agent for performing the work now carried on by the burning of coal, either for industrial or domestic purposes, and it is at least a debatable proposition whether our local authorities would not be justified, from the public health point of view alone, in selling electricity for domestic purposes even at a loss in view of the tremendous benefits to be obtained by abolishing the smoke cloud over our cities and towns. Dr. Ferranti's remark at the Scottish Local Section dinner two years ago is worth recalling. He said that "the smoke nuisance in our cities would be abolished as soon as the people realize that a pure atmosphere is worth paying for."

DUBLIN LOCAL SECTION: CHAIRMAN'S ADDRESS.

By G. MARSHALL HARRISS, Member.

(Address delivered 14th November, 1913.)

It is customary on an occasion such as this to review the work of the past 12 months and the works in progress and contemplated, and to form some opinion as to the state of our profession generally and its prospects for the future. At the present time I am afraid we are not in that easy condition of mind necessary for the calm consideration of these matters; for we have experienced nearly three months of the effects of labour unrest in this city, and we are still unsettled.

Apart from these troubles, the prospects for our profession are highly satisfactory. It is true there are not many recent undertakings of any considerable magnitude, or of exceptional nature to which to point. This is not because the resources of the electrical engineer are in any way exhausted, or that the limits have been reached in the useful application of electricity; for every year adds further proof of the great flexibility of electricity as a medium for the transmission of power on commercial lines over great distances and for all possible purposes.

No doubt the Board of Trade Regulations prohibiting the use of bare overhead wires carrying high potentials have been largely responsible for keeping back the progress of electricity supply from large central stations over wide and thinly populated areas. These regulations are being steadily relaxed, and municipal undertakings now

stand most in the way. Much as we owe the municipal authorities for their early enterprise in the development of electricity for lighting and other purposes, we are now confronted with the fact that they stand in the way of expansion. They themselves are unable to go far afield by reason of the fact that their powers are restricted to limited areas, and their trading instincts prompt them to prevent anyone else from undertaking this work, as instanced by the vigorous and successful opposition to the recent Power Bills. But the great central power stations must come sooner or later, and the sooner the better for the country at large and incidentally for the electrical engineer.

If we have not many recent large works to point to, we have nevertheless been doing good work. Electrical engineers have of late more settled down to the work in hand, and they have been directing their attention more to keeping in order and improving the appliances available than allowing themselves to be carried away by attractive and untried ideas and inventions; and as a result substantial progress has been made in matters of detail, which means progress upon proved lines.

In traction work, especially as regards street railways, or tramways, great progress has been made; not, however, in the mileage of lines added, that being insignificant, but in the ever-increasing number of passengers carried.

According to the last Board of Trade returns there were 220 millions more passengers carried than in the previous year. On the railways there has been a great falling off.

The Municipal Tramways Association, who present much valuable matter in connection with tramway development, devoted most of their attention at their recent Sheffield Convention to the commercial side of the question rather than the engineering side. From that it is not to be assumed, nor is it suggested, that the last word has been said in tramway design; on the contrary, the present time finds all the large undertakings, especially the older ones, busily engaged in their workshops, not merely maintaining and adding to their rolling stock, but re-designing it so as better to meet the increasing demands. The tendency is for larger cars, covered in tops, and faster running, all of which call for more powerful equipments, while in the light of increasing knowledge defects are being guarded against and improvements introduced, and in this way much sound and useful engineering work is being done.

Where new track is being laid, or old work renewed, the tendency is in the direction of heavier rails and more costly work all round, with the object of making the installation as permanent as possible. In the overhead equipment and its general construction and in the methods of distribution of electrical energy and its control, very few changes have been made or called for in recent years; indeed, in that direction the early engineers did their work well, and perhaps no part of a tramway system has given less trouble or more satisfaction. Phosphor bronze and other alloys exploited by different manufacturers of repute are largely finding favour in the replacement of trolley wires, originally of hard drawn copper. In the matter of "conditions" a most important matter to both tramway undertakings and the public is the recent agreement of the Postmaster-General to use covered wires instead of bare wires in all cases where the Post Office wires cross the tramway overhead lines, so doing away with the necessity for guarding the trolley wire in such places with the cumbersome and dangerous network of steel stranded wires.

In the generating station the increasing cost of coal calls for the engineer's more careful attention every day. Efficiency in every direction is of growing importance, and coal-saving devices, either not before developed, or not before considered worth adopting, have now to be carefully investigated. The reciprocating steam engine is giving way to the steam turbine, but it still has a place and is doing excellent service, particularly when working in conjunction with turbines of the exhaust or mixed-pressure type; indeed, where so arranged and under suitable conditions, results equal to the very best for low coal consumption are being obtained.

Engines of the internal combustion type, notwithstanding their enormous success and extended use for small powers, are now no nearer finding a place in the large power stations than they were some years ago. Steam as a medium for power production still holds the premier place. Development with a view to greater economy points at present in the direction of higher pressure and superheating to a degree far in excess of anything we have heretofore been accustomed to; the consequences in this direction cannot be viewed without apprehension, for the

necessity for better material, a higher class of workmanship, more costly maintenance charges, and more careful attention, will increase with the pressure and temperature, while the results of any failure in any of these matters will be magnified. At best the life of the whole of the apparatus must be shortened and the first cost and cost of maintenance and operation increased.

In the boiler house we have still enormous losses going on, and perhaps less has there been done and there is more room for improvements than in any other part of the power station. But in that direction the Bonecourt boiler, which is designed for gas firing, promises almost to revolutionize the methods of steam raising; it opens the door to all fuels, such as peat and sewage sludge, and while an efficiency of 92 per cent is claimed for the boiler, valuable by-products can be recovered from the gas producer.

In electrical machinery the improvements in rotary converters are valuable. Some advancement has been made towards the development of the single-phase motor. If this can be perfected to the same extent as the continuous-current or the polyphase motor it will widen the economical range for power transmission and greatly lessen the difficulties connected with distribution. With cheap fuel, whether at the pit's mouth or in this country at the bog side, and with improvements in boilers or gas engines, and with a satisfactory single-phase alternating-current motor, perhaps we may yet see electricity largely used in the cultivation of the land, thereby becoming the means of solving a great economic difficulty in that direction.

The farmer's margin of profit is so small and the amount of manual labour required in farming is so large that labour can only be poorly paid. The farm labourer's work is unattractive to young men, not on account of the small pay, but because the prospects for advancement are remote. Cheap power in a flexible form would lighten and cheapen the drudgery work, permit of higher pay for labour, and open a field for the exercise of intelligence of a high order; in this way, perhaps, electricity may eventually do more to bring the people back to the land than any legislation that can be devised.

I should like to say a few words on the subject of accounts and records. It might at first sight appear that there was no necessity for any more figures, on the grounds that those available are sufficient to enable us to analyse the different undertakings in every way that is of practical value. In the main I agree with this, but in one very important direction I venture to suggest we are working very much in the dark; I refer to the money we are spending on the upkeep of machinery, and the absence of records to enable us better to judge of the value we are getting for the expenditure.

It is a matter for judgment, backed by experience, as to what is the best way to spend money on each piece of machinery to keep it working efficiently. We usually class money spent in this way in part or entirely under any of the heads "maintenance," "repairs," and "renewals." These terms explain themselves, but the difference between them is not generally understood.

The object I have in view is to suggest a simple way of keeping records, which will show in each case what was in the mind of the man directing this expenditure and so provide a means for testing his judgment, incidentally enabling us to ascertain the value of each particular machine at any

time, as affected by the work it has done, and the money that has been spent on keeping it in order. It follows that if we can get so far, we shall also have a means for finding from our records when the useful life of any machine is approaching its end, or when it has reached the end of its economical life.

The system I propose involves the opening of an account for each separate unit or piece of machinery, and in these accounts the money spent on that unit is assessed as follows:—

Under "Maintenance" put the cost of any minor parts that regularly wear out more rapidly than the whole, being common more or less to all machines of the same kind, such as re-lining bearings with white metal, new brushes for a motor or generator, etc.

Under "Renewals" charge any part that is put in complete and which leaves the unit as a whole (making allowance for wear and tear) in the condition it would be when the whole was new; that is to say, the unit must be at least as good, if not better, after the new part has been added, as in the ordinary way it would be had the new part not been necessary. There is no limit in size or cost as to what may be properly considered a renewal. A new set-screw might be so assessed if the addition did not involve serious cutting away of metal in re-tapping to receive it, or doing anything else calculated to weaken some other part; but if when it is put in it is liable to want changing again before the whole wears out, it then cannot be charged as a renewal.

It is not necessary that a renewal should be always made with an absolutely new part. For instance, a machine may be in such a condition that taken as a whole the installation of a complete new major part would not be justified. In such a case, if there be available a part that had been taken from another machine and its installation will make the whole uniform as regards life, then this cost may be assessed as a renewal. Credit would also be allowed for a part taken out of a machine when that part either has a scrap value or is available for use again after repair.

Under "Repairs" must be put everything that is done other than "maintenance" or "renewals." A unit as a whole is always somewhat worse for everything that is done to it which cannot be properly charged under the other two heads. For instance, if any of the journals get scored and have to be turned up, that is a repair. Rewinding part of an armature or field-coils, turning up commutators, and such matters, are repairs. If any part is fractured and is mended in any way, this brings down the value of the whole, and on that ground is a repair. When a part that has been repaired is renewed, the cost of such repair no longer stands against the unit, and it is left out of consideration in arriving at its value. In the accounts kept in the above form a very accurate analysis of the expenditure would exist. They would contain a record as to the amount of money spent on each unit and the direction in which it went.

A ready means for arriving at the actual value at any time would be provided by deducting the depreciation from the original cost and adding the scrap value, depreciation being arrived at in the following way:—

$$\text{Depreciation} = \frac{\text{Original cost of machine} \times \text{Time working}}{\text{Lifetime}} + \text{Depreciation due to the nature of the repairs standing.}$$

The original cost and the length of time in use are figures which are available. The life-time, if not settled, would be arrived at in whatever way experience showed to be the best.

As to the Institution, I do not know what are the actual results of the recent changes in our constitution as regards making test examinations compulsory before admission, and the creation of the "Graduate" class. No doubt this latter has already brought in, and will continue to bring in, many desirable men who otherwise would not have been reached. I do not think there is any room for question as to the soundness of the principle aimed at. This is only a means to an end, the end being to raise the status of our profession.

We have followed the lead of the Institution of Civil Engineers in introducing entrance examinations, which was advocated by this Section in 1911. This is good, but we should go further. The solicitor's clerk is not a solicitor, the apothecary's assistant is not an apothecary, the apothecary is not a doctor, the sexton is not in Holy Orders, and the mechanic who makes up false sets of teeth is not a dentist. They cannot call themselves such, they cannot act as such by law; but the plumber, the wireman, the engine driver, the commercial agent of a manufacturer, are all "engineers," and can and do act as engineers, and can and do recover fees as such, independent of qualifications.

How can this be mended?

If there were no precedent it might seem hopeless to evolve order and create a profession out of the present chaos. Fortunately we have in the Medical Act of 1858—barely 50 years ago—an example of how the thing not only can be but has been done. In that year the medical profession was in much the same state as the engineering profession is now—with no standard of qualification and no legal rights. In that act no injustice was done to anyone than earning his living as a bona fide medical practitioner; and if we follow suit, any Act sought by us must fulfil the same condition.

By the courtesy of the Dublin Medical Registrar I have obtained a copy of the medical register from which I get the following information.

On 2nd August, 1858, an Act of Parliament was obtained for the medical practitioners, so "that persons requiring medical aid should be enabled to distinguish qualified from unqualified practitioners," the object of which was to raise the status of the profession of medicine and surgery by making it illegal for anyone to practise unless registered as the possessor of bona fide qualifications. The Act after providing for the formation of a medical council and branches and the appointment of a registrar enacts (Section 15) that every person then possessed of certain qualifications described in the Schedule (A) should upon payment of a fee be entitled to registration.

Section 18 provides that any person who was actually practising medicine in England before 1st August, 1815, or some 33 years before the passing of the Act, was entitled to registration upon making a declaration to that effect. While the Schedule A referred to provided for the taking in of everybody who had any reasonable qualifications for recognition.

Section 31 gives power to every registered person to

practise medicine or surgery or both, as the case may be, according to his qualifications, and confers certain rights as to the recovery of fees by law, but legalizes such by-laws as may be made by any College of Physicians preventing its Fellows or Members from suing for fees.

The next section provides that only registered persons can recover fees by law.

Section 36 sets out the appointments that an unregistered person cannot hold. These include every public appointment that is of standing, such as physician or medical officer to the Military or the Navy or any Public Institution, Friendly Society, etc., while Section 37 enacts that no medical certificates will be valid unless signed by a person registered.

Section 40 enacts that any person who shall wilfully and falsely represent himself as registered when he is not shall upon conviction pay a sum not exceeding £20.

Section 46 provides for persons practising abroad.

This early Act was amended twice in 1858, once in 1862, once in 1868-73, twice in 1875, and once in 1876-83, and it was repealed three years later. The last amendment Act is, I think, that of 1905, giving power to extend portions of the Medical Act of 1886 to the Colonies.

None of the subsequent Acts departed from the original

purpose of the Medical Act of 1858; on the contrary, except that the powers were made to reach further, and ladies were allowed to qualify for registration (the Medical Act Royal College of Surgeons of England, 1875), the subsequent Acts strengthened and further raised the status of the medical practitioner.

The Perjury Act of 1911 (1 & 2 Geo. 5, Cap. VI.), Sections 6, 7, and 17, gives power to punish persons, aiders, or abettors, etc., for making false declarations, by imprisonment or fine or both in respect to attempts to procure false registration.

Before the year 1888 the dentists, like the early physicians, seeing that their profession was being encroached upon by unqualified persons and that those qualified were without any protection or distinction, got together, and as a result an "Act to amend the law relating to dental practitioners" was passed in that year.

This Act is not so useful to the dentists as the Medical Act of 1858 is to the doctors. It is, I understand, shortly to be amended, but to do this successfully now and secure a useful instrument, no injury must be done to those already established.

The way to raise the status of the engineer is to make the profession recognized by law. The way to do this has been shown us.

THE BRITISH STANDARD SPECIFICATION FOR CONSUMERS' ELECTRIC SUPPLY METERS.

By S. H. HOLDEN, Member.

(Paper received 15th September, and read before the BIRMINGHAM LOCAL SECTION 12th November, 1913.)

The British Standard Specification No. 37 was published in 1907. In the opinion of the author this Specification has not so far taken the position in relation to the electricity meter industry which it is desirable that it should do; and he proposes to make certain suggestions which it is hoped will tend to the greater usefulness of the above specification.

There are three sections of the community who are interested in this matter: the manufacturers, the electric supply authorities, and the consumers. Manufacturers have much to gain by a general adoption of a standard specification among their customers, and having arrived by experiment and competition at a satisfactory design which complies with certain definite conditions, they would be saved the inconvenience of constant alteration of their manufacturing processes consequent upon the present system of individual specifications. There will probably always be a certain number of people who will insist on drawing up their own specification, but extension of the Standard Specification would abolish the necessity for this in many cases. The preparation of specifications for electricity meters is quite special work, and it is curious to notice how frequently engineers of ability are

betrayed into ridiculous mistakes when they attempt to draw up such a specification.

A further advantage of the general adoption of the Standard Specification is that foreign and colonial purchasers buying either direct or through merchants at home would know that if a meter complied with the Specification it was the best obtainable, and on that account standard English-made meters should enjoy a readier sale and command better prices than those supplied by competing manufacturers.

If consulting engineers and large purchasers were to adopt the same Specification they would save themselves much unnecessary work, and they would avoid the mistakes consequent upon specifying goods when they have not sufficient experience or knowledge of the real requirements. They would also incidentally help to keep down the cost of meters to their clients by avoiding a multiplicity of patterns.

It is essential that a standard specification should be thoroughly up-to-date; this necessarily involves fairly frequent revision. It should also cover all points relating to electricity meters which ought to be specified in the interest either of the manufacturers, the purchasers, or the

consumers; and it should be sufficiently rigorous to exclude all but the best articles. There may be many purposes for which a cheap and inferior meter is useful, but there should be a clear understanding that such meters do not comply with the British Standard Specification.

In the original Standard Specification no attempt was made to differentiate between alternating and continuous-current meters. It is desirable, however, to do so, as it is possible to obtain greater range and accuracy with an alternating-current meter having a pressure coil than with a continuous-current ampere-hour meter; and the best obtainable performance should be specified for each class of meter.

The following alterations and additions to some of the clauses, with one or two new clauses, are now offered for consideration and discussion. Where necessary the clauses have been printed for reference.

Clause 2. "The following capacities, in amperes, shall be recognized as Standard: 3, 5, 10, 25, 50, 75, 100."

The 2½-ampere size is preferable to the 3-ampere size for single-phase meters. The list of sizes should be increased by adding 150, 200, 250, 300, 400, and 500, ampere. The 75-ampere size does not appear to be really necessary.

Clause 3. "The meter shall be contained in a substantial dust-tight metal case of sufficient strength. . ."

After the word metal case it is proposed to insert the words "of cast iron or pressed steel." Cases of soft metal or sheet jointed together are not used on the highest class of meters.

Clause 6. This clause deals with the terminal box, but only specifies the size of the pressure-circuit terminal. It is therefore proposed to add "The main terminals shall each have two clamping screws. The depth of the hole into which the cable is inserted shall be at least twice its diameter. The following shall be the diameters of the holes for the cables: 10-ampere, 0.22 in.; 25-ampere, 0.32 in.; 50-ampere, 0.375 in.; 100-ampere, 0.435 in.; 150-ampere, 0.5 in.; 200-ampere, 0.6 in.; 250-ampere, 0.7 in.; 300-ampere, 0.8 in.; 400-ampere, 0.9 in.; 500-ampere, 1 inch.

Clause 10. "The meter shall have a suitable place and means upon the front of the case adapted to receive and secure a label to be provided and fixed by the purchaser or his representative. The purchaser's label shall be a rectangular sheet two inches long, half an inch wide, and not more than one thirty-second of an inch thick."

To this should be added: "It shall be affixed by two rivets, and the manufacturer shall provide two holes $\frac{1}{8}$ in. diameter and $1\frac{1}{2}$ in. apart in a suitable position for this label." It is doubtful, however, whether the size specified for the purchaser's label is large enough.

Clause 11. "The dial plate shall indicate the total consumption directly in units, either by means of a number of index hands each travelling round a circular dial on which divisions are marked and figured to indicate units, tens of units, etc., or by means of counter wheels on which digits are marked to indicate units, tens of units, etc., provided that only one digit on each counter wheel shall be visible at a time."

The addition suggested to this is: "If the latter is adopted, the figures on all the wheels shall spring suddenly

into position with the exception of those denoting units, which may move at a uniform speed." A counter which can allow of any doubt as to which of two figures is to be read on the higher multiples is inadmissible.

Clause 12. "The fastest-moving index hand or counter wheel shall indicate one unit per division or per digit, and the dial plate shall bear a statement to that effect. A convenient testing index shall be provided in addition, which shall be quite distinct in appearance from the dial proper."

The expression "kilowatt-hour" would be better than "unit," and the number of testing dials should be specified. It is therefore proposed to add: "Meters having a capacity of 2 kilowatt-hours per hour and under to have two testing dials reading $\frac{1}{10}$ and $\frac{1}{100}$ kilowatt-hour per division respectively. Meters above this capacity and up to 200-kilowatt-hours per hour to have one testing dial reading $\frac{1}{10}$ kilowatt-hour per division."

Clause 16. "The main circuit of the meter shall be so constructed that the total loss of power at full load as measured at the main terminals shall not exceed 15 watts subject to the further restriction that the loss of pressure in the main circuit at full load shall not exceed 2 volts in any meter."

As this specification does not apply to electrolytic meters, the 2-volt limit is far too high; $\frac{1}{2}$ -volt is ample. Most engineers prefer to be furnished with definite figures for each size of meter for the fall of potential at full load; the following schedule is therefore suggested:—

2½ or 3-ampere size...	...	0.75 volt
5 "	" "	0.50 "
10 "	" "	0.40 "
25 "	" "	0.30 "
50 "	" "	0.20 "
100 "	" "	0.10 "
150-ampere size and upwards		0.075 "

It does not seem necessary to specify exactly any figures below 0.075 volt.

Clause 17. "The pressure circuit, if any, of the meter shall be so constructed that the total power spent in it shall not exceed 4 watts for each hundred volts of pressure. The pressure circuit shall be connected to the supply side of the main circuit and a disconnecting device shall be provided in the terminal compartment to enable the pressure circuit to be entirely disconnected from the main circuit in order that it may be supplied with current from a separate source when necessary for purposes of testing."

The consumption of energy allowed by this clause appears to be far too high. The consumption in the pressure circuit of single-phase meters should not exceed 2 watts, and for continuous-current meters 7 watts, at the declared pressure, provided this does not exceed 650 volts.

Clause 19. This deals with starting currents. A first-class single-phase meter should start with $\frac{1}{2}$ per cent of its full-load current at a power factor of unity. A continuous-current ampere-hour meter should start with 0.05 ampere if of 10-ampere capacity or under, and with $\frac{1}{4}$ per cent of full load if over 10-ampere capacity.

Clause 20. "The error of a meter when tested at the marked temperature, pressure, frequency, and unit power

factor shall not exceed two-and-a-half per cent at any part of the range from full load down to one-tenth of full load. At any part of the range below one-tenth of full load down to and including one-twentieth of full load the percentage error shall not exceed the figure which is obtained by dividing, by four, the denominator of the fraction expressing the proportion the load bears to the full load, that is to say, at $\frac{1}{N}$ th of full load the error shall not exceed $\frac{N}{4}$ per cent."

This stipulation appears to be insufficiently rigorous and too clumsy for ordinary use. Alternating-current meters can easily be made within 2 per cent from one-twentieth full load to full load; and the same applies to continuous-current ampere-hour meters except that the lower limit should not be less than half an ampere. No guarantee of accuracy above or below these limits should be asked for or given.

Clause 25. "When a meter has a pressure circuit a variation of 10 per cent above or below the marked pressure shall not cause an error in respect of such variation of more than 1 per cent."

Clause 26. "When a meter is intended for use on an alternating-current circuit a variation of 5 per cent above or below the normal frequency shall not cause an error in respect of such variation of more than 1 per cent."

Clause 27. "When a meter is intended for use on an alternating-current circuit a variation in the power factor of the load from unity down to one-half shall not cause an error in respect of such variation of more than 2 per cent."

Clauses 25, 26, 27, all appear to lack definiteness, as the author has found that different interpretations are put upon them. The most usual interpretation leads to the absurdity that if, say, a meter is 2 per cent slow at normal voltage and a 10 per cent rise of pressure makes it correct, it must be rejected because the rise of pressure has caused more than 1 per cent variation, while if the same rise of pressure

makes it 1 per cent slower (that is 3 per cent total error) it will be accepted. It is suggested that the words "shall not cause an error" be altered to "shall not increase an error."

Variation of Wave-form.—This is not dealt with in the Standard Specification, but it is not unusual for consulting engineers to specify that meters shall be unaffected by variations of wave-form. The author, however, never came across a specification in which variations of wave-form were defined or limited. As a matter of fact alternating-current meters should not be affected by such variations in wave-form as are usually met with in practice. For the sake of completeness it is suggested that a clause be inserted to the effect that a variation of wave-form of 10 per cent from a true sine curve at any point shall not increase the error of the meter by more than 1 per cent.

It may be pointed out that slight additions to the Specification would make it cover polyphase meters; and in view of the large number of such meters in use their inclusion is very desirable.

At the conclusion of the Specification there is a note to the effect that an appendix, which would apparently deal with some of the points raised in this paper, was in preparation; so far, however, it has not been published.

In conclusion, the author suggests that the Institution should urge the Engineering Standards Committee to publish, as soon as possible, a revised and completed Specification for electricity meters, and that with a view to its wider use and circulation the price should be reduced to one shilling per copy in order that manufacturers may be able to include copies with their tenders. Those purchasing or specifying meters should also be urged to make use of the full Specification, without additions as far as possible, especially when meters are purchased for export. And some distinguishing mark should be placed upon meters which are sold as complying with the British Standard Specification.

A TWO-RATE TARIFF SYSTEM WITHOUT TIME-OPERATED CONTROL.

By H. H. PERRY, Member.

(Paper first received 9th September, and in final form 28th October; read before the MANCHESTER LOCAL SECTION 18th November, 1913.)

It is only within the last few years that electric heating and cooking have been energetically brought to the knowledge of the consumer by supply authorities. The reason for the tardy introduction no doubt lay in the untrustworthiness and poor efficiency of some of the apparatus. Vigorous efforts by manufacturers, however, have now opened up an entirely new field.

In Mr. T. P. Wilmshurst's paper¹ it was shown that there were three different periods at which a peak occurred for heating, and the chart areas of those peaks on the load curve were not appreciably dissimilar. One of the peaks coincided with the lighting peak.

A similar and perhaps more striking instance is afforded in the case of Luton, where the claims of electric heating and cooking are afforded full scope. For the past year the output has risen from 2,079,000 to 4,542,000 units, a 52 per cent increase, and the load factor from 19.7 to 20.9, i.e. a 6 per cent increase, under the "Point Five" tariff. As in the case of Derby, three heating peaks occur each day, the highest being at mid-day, while the Sunday load is a valuable one.

If, therefore, the average diversity factor is such that the heating peak-loads can be ignored, the problem still remains of basing the high-rate charges on the lighting only. It seems ridiculous to charge at certain times of the day a low rate for power and another rate for lighting for the dual supply, and further, it is equally absurd to exact the full penalty price from a consumer when he is using only a fraction of his maximum lighting load, assuming for the moment that no heating is in use.

In none of the papers which have been read before the Institution in recent years on the subject of tariffs is any suggestion made that the price charged for domestic lighting should, at any period of the day, approach or equal that charged for power except during restricted hours.

The object of this paper is to show:—

1. That the use of electricity can be extended, with advantage both to supplier and consumer, by granting facilities to the latter for using his lighting circuits during "off-peak" hours at a low-rate charge; and
2. That the multiplication of domestic power circuits, while being an advantage, is not always necessary for securing a low-rate charge.

A simple change-over switch, automatically rocked, can combine or separate the two rates at will. Such a method needs two meters and therefore resolves itself into a

TWO-RATE SYSTEM.

Up to the present, 2-rate clock or centrally controlled

systems have not made great headway for the following reasons:—

1. The high cost of meters (clock controlled).
2. Expert workmen are required for clock repairs.
3. Monthly winding.
4. Prolonged period of testing.

And in the case of central control by a system of mains:—

5. High initial outlay.
6. Cable faults.

There is another form of 2-rate meter with two sets of train wheels alternately geared to a single meter and controlled by a series solenoid energized by the lighting-circuit current. This was patented as far back as 1898, and made by the British Thomson-Houston Company, but I understand that its manufacture has been discontinued. It is obvious that such conditions can only apply to motor meters.

In all the above methods of operation, it is not possible to register on both rates simultaneously.

But why go to the expense of any of the above systems in order to change a consumer's meter over from the high rate to the low rate when a magnetic change-over switch will automatically do this?

DESCRIPTION OF SWITCH.

As shown in Fig. 1, an ordinary single-pole change-over switch is employed, one arm of which is magnetically attracted by the lighting-circuit magnetizing current. It is freely pivoted about its centre, and a balance weight is provided on the other arm, the position of which is adjusted to give any proportion of the consumer's lighting between, say, 5 per cent and 25 per cent at the low rate. In isolated cases it may be practicable to give a higher percentage.

Auxiliary contacts are provided for maintaining continuity of the circuit when changing over; without these, the practical everyday working of the switch would be impossible. No mercury cups are used.

Demagnetizing turns on the magnet, or a separate counter-magnet, are provided for the purposes to be described in connection with Fig. 4.

The switch is normally on the low-rate side, and two of the ordinary stock pattern of meters are employed, a practice which is daily becoming more common for domestic circuits owing to the demand for power.

Figure 2.—These connections would be used for a consumer taking practically all his current for lighting, no separate circuit being provided.

All the current passes through the high-rate meter

¹ *Journal I.E.E.*, vol. 51, p. 180, 1913.

(H.R.M.) or the low-rate meter (L.R.M.), and the switch is adjusted by the balance weight or by the air-gap so that all currents less than a given fraction of the maximum current (5-25 per cent) are registered on the low-rate meter.

Figure 3.—A separate power circuit is used, connected to the switch as shown, and two meters are therefore necessary under ordinary tariff conditions. The low-rate meter (L.R.M.) will therefore register the whole of the power load, and up to 25 per cent of that required by the lighting, when the switch is on the low (or left-hand) side.

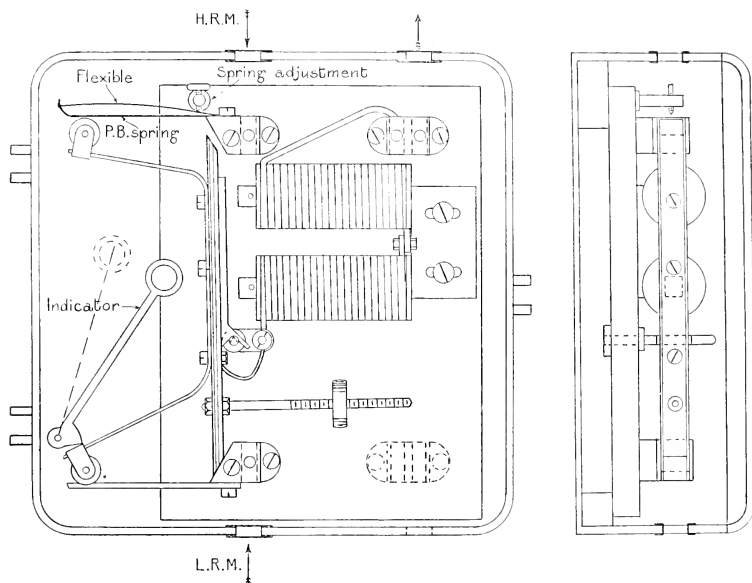

FIG. 1.—Two-rate Switch.

When the switch is on the high (or right-hand) side, L.R.M. will meter the power only, and H.R.M. only the lighting. Both in this case and in Fig. 4 the meters are required to operate simultaneously.

Figure 4.—The consumer has the option of these connections provided certain heating apparatus, such as a complete cooker, a system of radiators, or other power, is adopted, whether purchased outright or hired.

So long as the heater system is in use, L.R.M. will meter all power and any desired proportion of the lighting, since the pull of the magnet is neutralized to the required

extent. Otherwise the operation is the same as in Fig. 3; that is to say, the lighting reverts to H.R.M. after 5-25 per cent has been exceeded.

To provide equal and opposite magnetizing ampere-turns with equal current flowing in each circuit would court financial ruin if the heating system were maintained over the lighting peak; it is probable, therefore, that the opposing forces would generally be designed so as not to have a greater ratio than 1 : 2, or even as low as 1 : 4, until heating apparatus reaches a very much higher point of efficiency and commands a ready sale to every consumer.

Provided always that the heating peak, assuming that there is one only, does not coincide with the lighting peak in magnitude and length of time, the arrangement of Fig. 4 should undoubtedly prove acceptable. The mere granting of a low flat rate for power by many authorities to-day is an admission that the diversity factor is large enough to allow the coincidence of double peaks to be ignored. It has the immense advantage of giving to the consumer the facilities for using dozens of forms of really useful appliances (together with light) from the existing lighting circuits at a low rate, and the load so provided should do

much to improve the load factor, especially during the two summer quarters.

In a 2-rate system it may be urged that the cost of two meters is excessive, especially for the small consumer, who does not, and is unlikely to, use any power, and is therefore connected as in Fig. 2. The answer to that point is that if such a consumer can (by the setting of the auto-

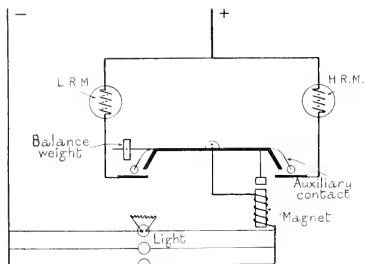

FIG. 2.

switch) save say 10 per cent on an annual bill of £5, he would agree to pay a small additional rental for a second meter. (See also "Appendix.")

If a consumer is connected as in Figs. 3 or 4, two meters are already necessary, and no additional expense is incurred.

There is nothing in this system to prevent the retain-

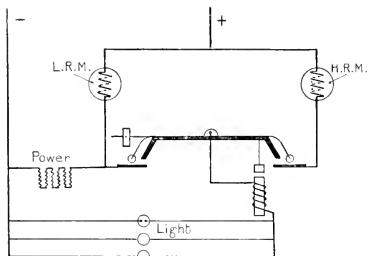

FIG. 3.

ment, or imposition, of a primary charge on the tariff, and it has been suggested that the cost of the auto-switch (about 17s. 6d. for the 10-ampere size) should easily be borne by the consumer in rental, or the tariff made to include it. There are many cases of "necessitated" lights, i.e. those which are the first to be switched on and the last to be switched off, and which ought to be distinguished from occasional lights. As already pointed out,

it seems misleading to charge a consumer an apparent high rate on these; I say "apparent" because he has little chance of ascertaining his real rate for these on the maximum-demand or primary-charge systems.

To give an instance. It is highly probable that a number of consumers would burn one or more lights throughout the night as a protection against burglary, provided that the cost were small and readily checked.

If heating by electricity is to be made familiar and profitable, it is a *sine qua non* that a hiring department be inaugurated from the commencement—not only from an introductory point of view, but as an educative agency always at the service of the consumer. It is well known to engineers that a watchful eye is generally needed for undersized plug circuits when heating appliances are in use.

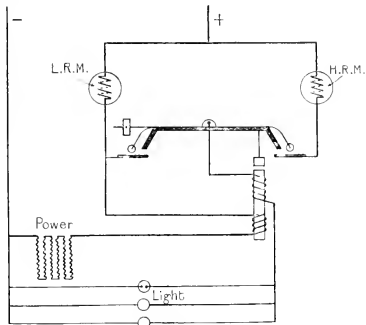

FIG. 4.

Before concluding, it may be useful to revert to a few points in connection with the instrument device, the working of which I have already explained.

1. The well-known effect of residual magnetism has prevented many devices in which instantaneous action is required for a small change in the current from being placed on the market. In the present case a much larger electromagnet than is ordinarily required is provided, and the air-gap is increased with but negligible magnetizing loss. The armature will rock to and fro with a change of only 0.3 ampere for a 10-ampere instrument.

The magnetizing loss at full load is approximately 4 watts with continuous current and 8-10 watts with alternating current.

2. The auxiliary contacts never have to carry more than 25 per cent of the lighting load, except when the arrangement of connections shown in Fig. 2 is employed and a large power load is carried, which is most unlikely. Both contacts are, however, designed to carry full load, so that continuity is assured; the top one only is provided with a flexible phosphor-bronze spring, which tends to give the consumer the benefit by resisting the connection with the high-rate meter.

3. Both auxiliary contacts are fitted with rollers, which relieve friction and tend to revolve with each rock-over motion. They are so pivoted that the break in the circuit as the position of equilibrium is approached is as short as possible. The inductive spark due to the magnetizing current is then negligible.

4. A simple indicator, governed by the magnetizing current, shows the rate in use. The balance weight can, if required, be sealed against fraudulent adjustment.

5. The complete switch in a sealed case measures 7 in. \times 7 in. \times 2½ in.

Whatever novelty may be claimed for this system I consider that it has at least the advantages of simplicity in working and a clear indication of the charges to be met by the consumer; the latter advantage I feel certain will be readily appreciated by him.

The reduction offered to consumers, whether taking power or not, is an inducement somewhat similar to that inaugurated by gas undertakings, and the increased business resulting would do much to reduce the standing charges.

APPENDIX.

Figs. 5, 6, and 7 show the methods of using one meter only for a 2-rate system and are intended only for 3-ampere or 5-ampere capacities, with reasonable accuracy obtain-

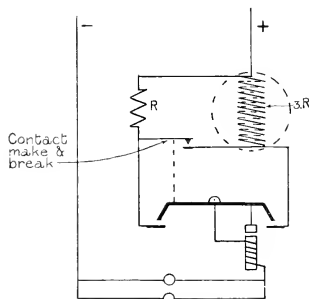

FIG. 5.—Ampere-hour Meter.

able at low powers. It is assumed that the average price charged will be 4d. per unit on the high rate, and 1d. per unit on the low rate.

Ampere-hour type.—The characteristic and resistance of the meter having been ascertained, the value of the shunt will approximate to the value R very closely if

$3R$ = resistance of meter + external resistance (if any),

In the case of a 5-ampere E.A.C. meter, the following result was obtained with 16-watt and 25-watt lamps:—

16 watts: 1 rev. in 45 secs. low rate.

4 " 40 " high rate.

25 watts: 1 " 21½ " low rate.

4 " 22½ " high rate.

The make and-break contact for the shunted current is actuated by the auto-switch, and the usual stock size

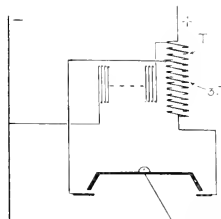

FIG. 6.—Continuous-current Watt-hour Meter.

of meter can be used without internal alteration for 2-rate use.

Continuous-current watt-hour type.—The field coils carrying the main current will be tapped in the ratio of 3 to 1,

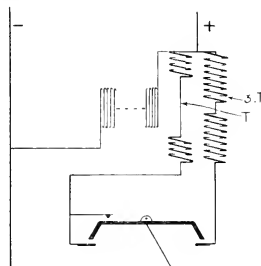

FIG. 7.—Alternating-current Watt-hour Meter.

so that the measurement on the high-rate side will be $3 + 1 = 4$.

This type of meter for small consumers is not generally used.

Alternating-current watt-hour type.—The field coils are split into two parallel circuits in the ratio of $\frac{3}{4}$ or $\frac{1}{4}$ to 1 according to the characteristic. The make-and-break contact is employed as in the ampere-hour type.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 13TH NOVEMBER, 1913.

Proceedings of the 556th Ordinary Meeting of the Institution of Electrical Engineers, held on Thursday, 13th November, 1913—Mr. W. DUDDLELL, F.R.S., President, in the chair.

The minutes of the Annual General Meeting held on the 30th May, 1913, were taken as read, and confirmed.

The PRESIDENT: Before proceeding to the business of the evening I have to refer to a matter with which many of you are already acquainted, namely, the great loss that the Institution, the electrical industry, and Telegraphy and Telephony especially, have sustained in the death of our Past-President, Sir William Preece. Sir William Preece was elected to this Institution in the year of its inception, 1871. He served as a Member of Council from 1873 to 1876, as a Vice-President from 1877 to 1879, and as President in 1880, and again in 1893. All who had the pleasure of knowing him appreciated his genial and kindly manner, and more especially his kindness to the younger members of this Institution. We have received a cablegram from the American Institute of Electrical Engineers expressing their regret at our loss and their loss, for Sir William was an Honorary Member of their Institute, and we have replied thanking them for their kind message of sympathy. I now ask you to pass a vote of condolence to his family, by all standing in silence.

The resolution was duly passed.

The list of candidates for election and transfer approved by the Council for ballot was taken as read, and was ordered to be suspended in the Hall.

Donations to the Library were announced as having been received since the last meeting from W. T. Anderson, Messrs. Babcock & Wilcox, C. A. Baker, F. Broadbent, The Canadian Department of Mines, Messrs. J. & A. Churchill, W. C. Clinton, A. G. Collis, Messrs. Constable & Co., A. Danvers, The Director-General of Posts and Telegraphs (India), The Electro-Technical Laboratory (Tokyo), The Engineering Standards Committee, A. P. M. Fleming, Professor J. A. Fleming, E. Garcke, Sir John Gavey, C.B., J. X. Gosselin, W. Hibbert, E. G. Hillier, H. M. Hobart, The Institution of Civil Engineers, D. Jaroslaw, E. Kohl, P. Laubach, Marconi's Wireless Telegraph Company, W. P. Maycock, The Meteorological Committee, W. H. Molesworth, Major W. A. J. O'Meara, C.M.G., Messrs. S. Rentell & Co., The Royal Society, A. E. Salazar, A. H. Seabrook, Messrs. Siemens Brothers Dynamo Works, Società delle Forze Idrauliche del Moncenisio, The U.S.A. Department of Commerce, L. H. Walter, W. H. Watkinson, B. Welbourn, and O. J. Williams; to the Museum from R. K. Gray, Mrs. A. F. Grimley, K. Hedges, P. Huddleston, Mrs. Jenkins, Major W. A. J. O'Meara, C.M.G., G. R. Taylor, Major W. F. Cooke Taylor, and C. E. J. Twissaday; to the Building Fund from G. M. Robertson; and to the Benevolent Fund from The Committee for the Protection of Electrical Interests, The Electrical Engineers' Ball Committee, The "25" Club, R. M. Sayers, A. D. Stevens, and W. C. P. Tapper, to whom the thanks of the meeting were duly accorded.

The PRESIDENT: It will be remembered that in 1911 a number of past and present members of the Council formed a Guarantee Fund amounting to over £7,500 to meet any contingency which might arise at any time before the 31st December, 1915. The Council are of opinion that the financial condition of the Institution is now such that the Guarantee Fund is no longer needed, and I therefore move the following resolution:—"That the subscribers to the New Guarantee Fund (1911) be released from their guarantees."

Mr. J. SHEPHERD: I beg to second that resolution.

The resolution having been put, and carried unanimously, was declared by the President to be carried.

The Scholarships and Premiums referred to in the Annual Report² of the Council for the year 1912-13 were presented, and the President then delivered his Inaugural Address on "Pressure Rises" (see p. 1).

Mr. ALEXANDER SIEMENS: After the very hearty applause with which the Presidential Address has been greeted, it is hardly necessary for me to emphasize how very grateful the Institution should be to Mr. Duddell for giving us, instead of a Presidential Address dealing with what may happen in the future, an

* *Journal I.E.E.*, vol. 51, p. 366, 1912.

Address like that of Professor Hughes, when he showed us a microphone, the foundation of the telephone of to-day. I am quite certain that the eloquence with which Mr. Duddell has described his experiments, and the beautiful order in which he has shown his apparatus, which did not fail once during his Address, have made a deep impression upon us, especially upon those who have had to make experiments themselves. I have much pleasure in moving: "That the best thanks of the Institution be accorded to Mr. Duddell for his interesting and instructive Presidential Address, and that with his permission the Address be printed in the *Journal* of the Institution."

DR. S. Z. DE FERRANTI: I am sure that all of us who have listened this evening to the President's Address have had the greatest possible treat that anyone could have who belongs to this Institution. To me the Address has been most delightful, and we are accustomed to judge the feelings of others by our own feelings. I think our President should be a very happy man to-night, because I know of no greater pleasure than that of being able to give considerable pleasure to a number of people. I beg to second the resolution.

The resolution was carried by acclamation.

After the President had briefly replied to the vote of thanks, the meeting adjourned at 9.48 p.m.

INSTITUTION ANNOUNCEMENTS.

PAPERS.

Papers (complete with all tables and illustrations) should reach the Secretary not later than the 31st July if the Authors desire that they should be considered with a view to their being read, if selected, in the first half of the Session (November, December, and January), and not later than the 31st October for the second half of the Session (February, March, and April).

The Papers Committee will also be pleased to consider at any time Papers for publication in the *Journal*.

ANNUAL DINNER.

The Annual Dinner of the Institution will be held at the Hotel Cecil, Strand, London, on Thursday, 5th February, 1914.

WIRING RULES.

The Wiring Rules Committee will be glad to receive suggestions (in the form of specific amendments) as to suitable points for consideration at the next revision of the Rules.

The membership of the Committee includes electricity supply engineers, consulting engineers, manufacturers, and contractors, together with representatives of the Fire Offices, The British Electrical and Allied Manufacturers' Association, The Cable Makers' Association, The Electrical Contractors' Association of Scotland, The Incorporated Municipal Electrical Association, and The Electrical Contractors' Association.

RESEARCH WORK.

Arrangements are being made by the Research Committee for the investigation of the following matters:—

MAGNET STEELS.

1. What is the relation between the percentage content of tungsten and the coercive force in tungsten steels, preferably in some one series containing a standard percentage, say 0.5 per cent, of carbon, all specimens in the series being quenched at one of the following temperatures, say 700° C., 750°, 800°, 850°, 900°?

2. Whether the presence in tungsten steel of manganese or of silicon is detrimental to either the remanence or the coercive force?
3. What are the magnetic properties of vanadium steel when the percentage of vanadium is varied while the carbon content is constant; and what when the carbon content is varied while the vanadium percentage is constant?
4. What are the magnetic properties of molybdenum steel when the percentage of molybdenum is varied while the carbon content is constant; and what when the carbon content is varied while the molybdenum percentage is constant?
5. Whether there is any relation, either in a high carbon steel or in a tungsten steel, between the ductility or the surface hardness and the residual magnetism?
6. What ratio of length to diameter is best for bar magnets made of some standard brand of tungsten steel?
7. Whether the transition temperature at which the steel regains its magnetic properties corresponds, in high-tungsten or medium-tungsten steels, to Ar, or to Ar₂?
8. Whether in high-tungsten steels the magnetic qualities are improved by a brief preliminary heating to temperatures between 900° and 1,200°, which are known to lower the recalcrescence point?
9. Whether any of the self-hardening steels of commerce are superior to the standard brands of tungsten steel in respect of remanence or of coercive force?
10. What, in the case of bar magnets made of any standard brand of tungsten steel, are the results upon the remanence and on the coercive force of maturing the magnets by prolonged heating in steam, as in the researches of Barus and Strouhal on carbon steel?
11. What are the values of the coefficients of self-demagnetization of horse-shoe magnets, and of those forms of magnet which are used in electricity meters?
12. What are the values of the temperature-coefficients for properly matured magnets of nearly-closed shapes, made of some standard brand of tungsten steel?

13. Whether, and in what way, the coercive force of a properly matured bar magnet, made of some standard brand of tungsten steel, depends upon the intensity of the field in which it was magnetized, or on the length of time during which it was subjected to that field?
14. What are the magnetic properties of ferro-tungsten, of ferro-molybdenum, and ferro-vanadium purified from the presence of carbon, silicon, manganese, sulphur, and phosphorus?
15. Whether, in a steel or pearlitic composition if heated to 700° and allowed to cool very slowly to 670° while in a strong magnetic field, the presence of the magnetizing forces will have any effect on the formation of the pearlitic structure?
16. Effects of physical treatment:—
 - (a) Distortion of specimens as a result of quenching.
 - (b) Loss of magnetism as a result of vibration.

INSULATING OILS.

Section A.—Chemical.

1. In any given transformer oil what is the relation between temperature and tendency to sludge formation in any oil exposed to the atmosphere?
2. Under abnormal conditions of specially high temperature in the laboratory what, for any given temperature, is the time required for the manifestation of sludge?
3. What laboratory tests can be devised to determine the amount of sludge produced under abnormal conditions of specially high temperature?
4. Whether the tendency to form sludge occasioned by high temperature and dry air or oxygen at one point can be neutralized by artificial cooling at another at any defined working temperatures?
5. Whether the tendency to form sludge can be neutralized by keeping the surface of the oil in contact with an inert gas such as nitrogen or carbon dioxide?

Physical.

6. Under normal working conditions what period elapses before the tendency to sludge formation is manifested in high-tension transformers?
7. What changes in viscosity, specific gravity, flash-point, relative thermal transference, dielectric strength, and specific resistance, accompany the formation of sludge?
8. How are the electrical properties of the oils and the formation of sludge affected by the circulation of air over their surfaces?
9. What is the temperature to which different oils can be raised repeatedly without appreciable change in their physical properties?

Chemical and Physical.

10. How do oils of different specific gravities and viscosities compare as to their liability to form sludge at temperatures of, say, 60, 70, 75, 80, 85, and 90 per cent of their initial flash-point?

Section B.—Chemical.

11. What is the amount of moisture which can be absorbed from the atmosphere by a dry oil at various temperatures, and how should such increment of moisture be determined?
12. What chemical or physical standard should be laid down as constituting a dry oil, and what changes in specific resistance and dielectric strength accompany increments in moisture?

Section C.—Chemical.

13. Did the usually accepted tests for the detection of acid, alkali, sulphur, resin, or resinoid materials lead to comparable results?

Physical.

14. In determining dielectric strength and insulation resistance what apparatus should be employed, how are different methods comparable, and what standard conditions, such as shape of electrodes, intervening distance, depth of immersion, movement, if any, of oil, etc., should be adopted?

Section D.—Physical.

15. Whether any practical means are in vogue for the laboratory estimation of the relative thermal transference in switch and transformer oils, what standard apparatus should be employed for such a purpose, and by what means should this property be expressed?
16. Is it at present possible to express the relative thermal transference of any oil at, say, 50°, 60°, 65°, 70°, and 75° C. as a function of its specific gravity and viscosity at these temperatures?

Section E.—Chemical.

17. What is the chemical composition of the gases (known to be highly explosive) which are liberated by an arc, and does their composition vary with different mineral oils?

Chemical and Physical.

18. Whether, and if so to what extent, the amount of carbon produced by an arc under any given oil varies with the temperature of that oil, or whether the temperature being kept constant, the amount of carbon produced varies with the specific gravity or viscosity of the oil, and if so, to what extent?

Section F.—Chemical.

19. Whether the production of traces of nitric acid or ozone by a silent discharge at the terminals of, say, 80,000- or 100,000-volt transformers causes any change in the chemical constitution of an oil in its vicinity or may render the oil more liable to absorb moisture from the air with which its surface is in contact?

THE HEATING OF BURIED CABLES.

An investigation to determine the temperature rise in, and the permissible current density for, buried cables.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 27TH NOVEMBER, 1913.

Proceedings of the 557th Ordinary Meeting of The Institution of Electrical Engineers, held on Thursday, 27th November, 1913—Mr. W. DUDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 13th November, 1913, were taken as read, and confirmed.

The list of candidates for election and transfer approved by the Council for ballot was taken as read, and was ordered to be suspended in the Hall.

Messrs. W. A. Mackenzie and H. C. Channon were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows:—

ELECTIONS.

Members.

Dawson, William Francis.
Thomas, Eustace.

Associate Members.

Allsopp, Charles Edward.
Bailey, David Edward.
Brooks, James Illingworth.
Bruty, Albert George.
Colin, Julius.
Davies, Herbert Abram.
Erlang, Agner Krarup.
Fairgrieve, William Augustine.
Hall, Frederick Charles.
Haslam, Lionel Frank.
Heath, William George.
Hendrey, William Graeme.
Herbert, Charles Meredydd.
Hurlblatt, Douglas Gray.
Inglis, Malcolm MacKinnon.
Ingeuville, Pedro.
King, Zunglich Dong.
Lawson, Wilfrid.
Licence, Francis Gilbert.
McArthur, Archie Wallace C.
Makins, Charles George G.
Morris, William Henry.
Mountain, Kenneth Arthur.

O'Brien, Claude Conroy.
Palmer, Charles Reginald.
Plank, Charles Selwood.
Pond, Thomas Arthur.
Preston, Frank Bennett.
Richards, Gilbert Howard.
Rouard, Louis Jean.
Simon, Horace Francis.
Starkey, Harold Augustus.
Stone, Harry.
Stuckenschmidt, Friedrich Georg.
Suggate, Chenery.
Warwick, John.

Associates.

Freeman, Horace.
Punter, James William.

Graduates.

Chatterjee, Bhim Chandra.
Coleman, Herbert Stoddard.
Das, Bhubanananda.
Goldthorp, Guy.
Keady, Thomas Pakenham.
Leggett, Bernard John.
Leivesley, Herbert.
Pearce, Charles William.

Pillai, N. S.
Rennick, Herbert Cumming.
Skittrell, Charles James H.

I. INTRODUCTORY.

During recent years a great deal of valuable research work has been done to increase our knowledge of the properties of insulating materials, yet notwithstanding the progress so made the natural laws governing insulation resistance are but little understood. So little, that if at the outset of this paper a plausible statement were made to the effect that the insulation resistance of an electrical system depended mainly upon the dielectric properties of the insulating materials, it might easily pass unchallenged. Possibly some objectors might be found among those who have to maintain the insulation of electrical plant; for no one who has had much experience of the behaviour of insulation in practice, could fail to be struck by the disparity between insulating materials under test in the laboratory and the same materials under the ordinary conditions of use.

It is, of course, easy to guess that the disparity is generally due to the presence of moisture, and in fact the only insulating materials whose behaviour in use corresponds with their predetermined dielectric properties are those which are non-absorbent. Of the remainder, and they form the majority of the materials in common use, we can only predict that the insulation resistance of any electrical system in which they are used will be governed almost entirely by the moisture they absorb. Everyone knows that insulation resistance decreases on a damp day and recovers during dry weather. It is perhaps not so generally known that in most cases insulation resistance decreases, in a perfectly definite way and almost instan-

taneously, as the electric pressure upon it is increased, and slowly recovers if the pressure is restored to the initial value or cut off altogether.³ The connection between these two facts is by no means obvious, yet they are so closely related that if we succeed in explaining one of them we shall certainly understand the other. It is often useful to attempt to explain familiar things; facts which, like the effect of a damp day on insulation, are so natural as to require no explanation—until we begin to think about them.

The effect of moisture, the effect of voltage, the effect of polarity, these and other phenomena commonly met with in insulation have been forced upon the author's attention for many years past, and the pressing need to find answers to the questions that so frequently arise in connection with insulating materials induced him to undertake an experimental research with a view to the better understanding of their behaviour in everyday use. This work has been in progress for three years, most of the time being spent in finding a firm basis for future work. But certain experiments have already thrown some light on matters which have hitherto been obscure, and the object of this paper is to render the knowledge so gained available for all those who are interested in the insulation of electrical plant. The specialist will find herein much with which he is well acquainted; but insulation largely concerns those who have no special knowledge about it, and on that account many things have been introduced into this paper in order to give a general view of the subject.

What is the margin between the working voltage and breakdown? That is the fundamental question at the root of every inquiry into the properties of insulation. If a definite answer is ever forthcoming, it will not have been found in "blind" tests of breakdown voltage. To conduct tests without any means for ascertaining what is going on in the insulator as the breakdown voltage is approached, without either observing the current or, better still, the resistance, is to shut our eyes and deliberately avoid looking for the cause of failure.⁴ The author has therefore sought, by investigating the nature of leakage conduction, to establish some definite relation between applied potential difference and insulation resistance. If the curve expressing this relation be traced from a few volts up to

* Since the first half of this paper was written, Mr. P. R. Friedlaender has drawn attention to the relation between voltage and insulation resistance, and has given a typical example in the form of a curve. (Communicated remarks in the discussion on Mr. Kayser's paper on "High-voltage Tests and Energy Losses in Insulating Materials," *Journal I.E.E.*, vol. 49, p. 79, 1912.)

† The flash test as applied to some costly piece of electrical apparatus must have been inspired originally by something akin to the heroism of the savage.

the breakdown point, it will be found to consist in general of two parts of opposite curvature more or less like the voltage-resistance curve shown in Fig. 1. The two parts of the curve will be joined together by an approximately straight line, the length of which varies greatly according to the nature and condition of the insulation. This connecting link is sometimes so short that the two parts of the curve appear to meet at a point of inflexion and they then form a sort of ogce curve.

The research had not proceeded very far before it was realized that the shape of the first part of this characteristic curve is determined by the extent to which leakage is due to moisture, and further that leakage through the substance

of the complete curve (see Fig. 1) is still in the preliminary stage, and the present paper deals mainly with the first part up to the point or region of inflexion.

2. METHOD OF INVESTIGATION.

To avoid encumbering the paper, methods of experiment will only be described so far as they are essential. As a preliminary, a few words must be said here in order to remove any misapprehension as to what it is that goes by the name "insulation resistance." When a conductor resistance is measured care is taken to avoid the introduction of any extraneous electromotive forces due to polarization, induction, capacity, or thermo-electric junctions. By so doing, the result of the test is a true measure of an inherent property of the conductor, namely the ohmic resistance apart from any other kind of resistance or opposition to the passage of an electric current. But with insulating materials similar precautions are not generally possible, and all that can be done is to measure the ratio of applied potential difference to the resulting current, V/I , and call that the insulation resistance. We may measure the two factors either separately by means of a voltmeter and a galvanometer, doing the division sum ourselves; or both may be measured at once by an ohmmeter which does the division sum for us. Either way the result is the ratio of pressure to current. It is customary to express this ratio in ohms or megohms, and there is no harm in doing so provided we realize that the "ohms" so obtained are not necessarily of the same nature as the ohms in a metallic conductor. Of course the true ohmic resistance of the insulator (if it has such a property) is included in the result of a resistance test, but it is so entangled with surface leakage, the effects of electrostatic capacity, and the penetration of electric charges into the substance of the insulator, that we are often obliged to be content to lump all these things together when we undertake the measurement of insulation resistance.

Resistances of very high value are often measured by charging the system under test and then observing the gradual fall of potential as the charge leaks away. But this method, being based on the assumption that the resistance of an insulator is independent of the potential difference, begs one of the principal questions the author set out to answer. Obviously it was essential to measure either the resistance or the leakage current.

In dealing with so unstable a quantity as insulation resistance there are obvious advantages in making direct measurements of resistance, and perhaps the greatest advantage of the ohmmeter method is the detection of instability immediately it occurs. But it was desirable to have the means of measuring up to about one million megohms at 500 volts, and at present the galvanometer is the only instrument possessing the required sensibility. The use of ohmmeters was therefore confined to tests which came well within their range, and the greater part of the work was done by means of a Broca galvanometer made by the Cambridge Scientific Instrument Company.

The galvanometer method gives no evidence of instability until the ratios of pressure to current are worked out at the conclusion of a series of tests, and the consequence of this lack of timely warning was that in many cases it proved to be impossible to plot a curve from the observations, just because the insulation had been in an unsteady condition

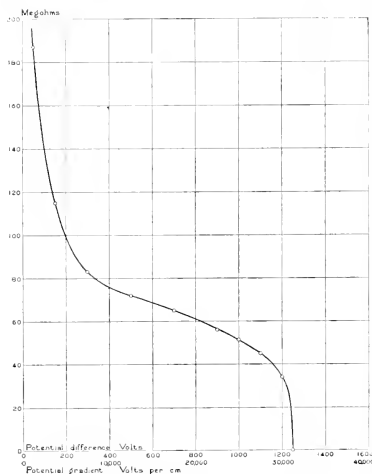

FIG. 1.—Complete characteristic curve for Cotton containing a normal amount of moisture absorbed from the air.

of the insulator—dielectric leakage—was negligibly small compared with that caused by the merest trace of moisture. This leads to the point of view that for most practical purposes an insulator may be regarded as having no inherent conductivity, the conducting power which it appears to possess being usually caused by leakage over damp surfaces. If the insulator is porous then the leakage surfaces are not only those outside the insulating body but those surfaces which bound the maze of capillary channels inside the porous material. If this idea be provisionally accepted at the outset the facts brought out by the experiments will be found to fall easily into their places, and a fairly consistent view of leakage conduction will be obtained. The research divided itself quite naturally into two parts corresponding to the two significant parts of the characteristic curve. The investigation of the second or breakdown part

during the tests. For this reason alone much fruitless labour would have been avoided had it been possible to use an ohmmeter throughout the investigation.

The pressure was supplied by a battery of secondary cells giving about 500 volts, and in a few cases this was supplemented by a small testing generator giving 1,000 volts. It should be mentioned that when leakage conduction is to be detected or measured, continuous current is essential. Quite apart from the greatly inferior sensibility of alternate-current instruments, the alternating current due to electrostatic capacity is generally much larger than the leakage current, so that the latter is difficult to disentangle and easily escapes detection altogether. Methods have been suggested by which the two currents might be separated and what is now impracticable may one day come into use, but at present continuous current has no competitor in this field.

Guarded insulation—the method of Price's guard wire extended to include every material insulating point in the testing apparatus—is now universal in insulation testing. This happy invention was of course used throughout the present investigation, and hence the current measured was in every case the current it was intended to observe and nothing else.

Before quitting the subject of methods of experiment, a minor precaution may be referred to. Every insulator has some electrostatic capacity, however small. In most cases this was inappreciable and the charging current could be ignored. But in every case in which a charging current

greater than the nature of the investigation required. The discrepancies that frequently occurred were almost entirely due to rapid and unavoidable changes in the insulator under test. Hence the accuracy of any set of tests was

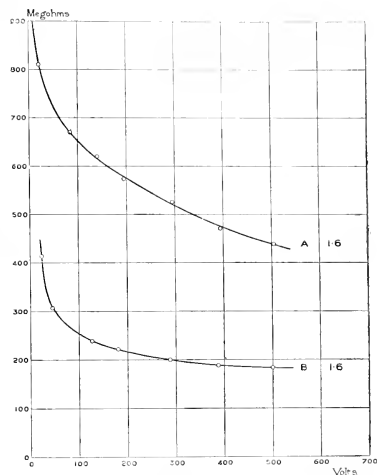

FIG. 3.—Insulation resistance of Field Coils: A, in dry weather; B, on a damp day.

often a matter of luck, and it was only upon a general review of a large number of similar tests that any sound conclusions could be reached. These remarks are all the more necessary because it is no uncommon thing to see insulation resistance expressed by a long row of figures, of which perhaps the first digit has something to do with the leakage current (and often much more to do with the charging current) and all the others have obviously been born of the slide rule.

3. TYPICAL EXAMPLES OF INSULATION.

Although it is impossible to predict the insulation resistance of any piece of apparatus, yet if each of the insulating materials had a resistance as constant as that of a metal we might reasonably expect the insulation as a whole to follow Ohm's law. A few typical examples will show how little ground there is for any such expectation. In the choice of examples it does not matter what kind of insulators are involved; so long as their resistance is within the range of measurement they will nearly all tell the same tale of a gradual fall in the resistance as the testing voltage is increased. Characteristic voltage-resistance curves, obtained from things which happened to be at hand, are given in Figs. 2 to 7.

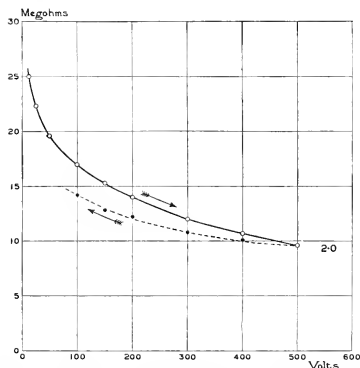

FIG. 2.—Insulation resistance of a Dynamo Armature, showing hysteresis effect.

was observed, ample time was allowed for it to die away to a negligible value before taking a reading of the leakage current.

Electrical measurement is capable of such precision that it was not easy to avoid aiming too high in this respect. Upon the whole the precision of the apparatus was much

It will be seen that in every case the resistance falls as the potential difference rises, although the curves differ in shape a good deal and the decrease in the resistance is therefore much less marked in some cases than in others. It will be shown later on that these obvious variations in the curves indicate differences both in the kind of material used for insulation and the condition as regards moisture. For example Fig. 2 is a typical moisture curve, indicating that the insulation is entirely composed of absorbent

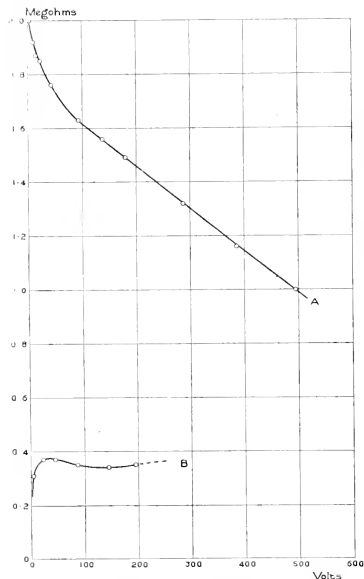

FIG. 4.—Insulation resistance of Lighting Circuits: A, in dry weather; B, in very wet weather.

materials. It is important to note that when the curve was retraced backwards a kind of hysteresis effect appeared. With absorbent insulators this effect is nearly always to be found if one chooses to look for it. The two curves in Fig. 4, one traced on a wet day and the other after a spell of dry weather, show that a large excess of moisture not only lowers the general level of the resistance but also brings about an entire change in the character of the curve. In the lower curve three things which are characteristic of conduction by moisture are struggling for the mastery. On a wet day every solid insulator is covered with a film of water which if it were in stable equilibrium would conduct according to Ohm's law and give a horizontal straight line.

But instability is a marked feature of films when they are exposed to the air, and hence in practice the curve is never a simple straight line. In addition there is some typical

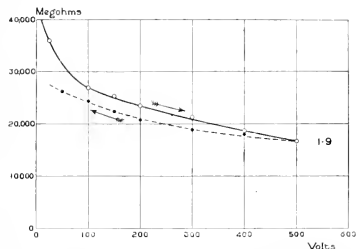

FIG. 5.—Insulation resistance of a moving-coil Ammeter in which the ebonite insulation had become defective from an accumulation of dirt.

conduction through absorbent insulators, and the curve is the resultant of all three effects.

In Fig. 5 the resistance was in an unstable condition, several discrepancies being noticed in the course of the tests. This curve being retraced backwards from 500 volts also shows the hysteresis effect.

The curve in Fig. 6 is typical of insulation that is made up of an absorbent insulator in series with one which has a more nearly constant resistance, and when the nature of moisture conduction has been examined we shall see how the resistance of these two components may be separated and an approximate value assigned to each. In short, we shall arrive at the tentative beginnings of a rough diagnosis of insulation. Fig. 7 is remarkable because it shows that the resistance was affected by polarity. When the testing

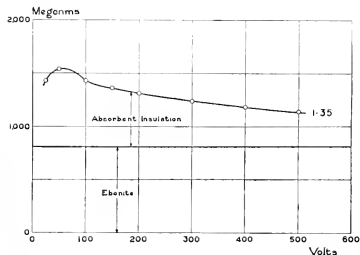

FIG. 6.—Insulation resistance of a Supply Meter, a typical example of absorbent insulation in series with a non-absorbent insulator.

generator was so connected that the circuit wires were positive and the earth negative, the resistance was 8.7 megohms; whereas when the polarity was reversed the

resistance fell to 5.7 megohms; both readings being those taken at 500 volts.

The polarity effect which has just been noticed in connection with Fig. 7 is a strongly marked characteristic of earthenware insulators, and although it has nothing to do with the characteristic curve some account of it seems to be called for in a paper on insulation resistance. But the subject cannot be dismissed in a few lines and to avoid a long interruption in our main argument the effect of polarity has been dealt with in an appendix under the heading "Insulation Valves." The matter is one which closely concerns everyone who has occasion to test insulation in which earthenware of any kind is used as an insulator.

Before any general hypothesis can be framed to account for the characteristic behaviour of insulation in ordinary

Figures may be found in the text-books for the specific resistance of various insulators. What may be called good insulators vary from about 80 million megohms for mica up to about 50,000 million megohms for vulcanized rubber—the centimetre cube being the datum. Such figures as these convey no more meaning to the mind than the distance of a star expressed in miles; we do not want figures so much as relative magnitudes. The consideration of an example of dielectric conduction will therefore be a useful preliminary because it will afford some insight into a subject which is but little understood outside the test room, and at the same time serve to create a proper sense of proportion.

The only non-absorbent insulators which were tested in the course of the work recorded here were gutta-percha and rubber. These are both non-absorbent in the sense that what little water they may be capable of absorbing is entirely unable to form leakage paths through the insulator. Submarine cables insulated with these materials have been lying on the bottom of the sea for half a century or more, and, so far as the author is aware, no trace of conduction by absorbed water has ever been detected in a sound cable.

Rubber as an insulator for cables is so extensively used in every branch of electrical industry that it is naturally the example chosen for illustration. The test sample was a rubber-covered flexible cable made up of 64 6-mil wires, insulated in accordance with the standards of the Cable Makers' Association, and guaranteed to have an insulation resistance of not less than 600 megohms for one mile after one minute's electrification. The rubber is between 35 and 37 mils in thickness, and consists of one layer of pure Para and two layers of vulcanized rubber. This flexible is used by the author's firm for the interior connections of naval gear and for that purpose it is supplied without any covering outside the rubber; it was therefore in suitable form for an under-water test. A length of this cable—equal to 1/16th of a mile—was put into a bucket of water, where it remained for 40 days. The tests which were made during that period consisted in charging the cable at about 500 volts and observing the total current flowing into it at intervals of time, so that a time-current curve might be drawn. Tests were also made by discharging the cable and observing that part of the discharge current which passed out through the galvanometer. It should be noted that whereas during the charging of the cable the entire charging current traverses the galvanometer, no equivalent statement can be made about the discharge current. During discharge there are three parallel paths for the current: through the galvanometer, through surface leakage paths at the exposed ends of the cable (the guard wires being ineffective during discharge), and lastly the dielectric leakage paths through the rubber. Hence the discharge as recorded by the galvanometer does not agree exactly with the charge.*

Suppose the cable is charged through a resistance of r megohms by a battery giving V volts, the dielectric resistance being R megohms. Then the leakage current will be $V/(R+r)$ micro-amperes, and the initial value of

* For the purpose of this paper it is not necessary to describe the ordinary method by which the leakage current is arrived at by deducting the discharge current from the total current flowing into the cable.

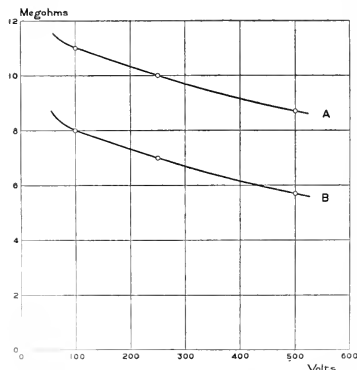

FIG. 7.—Insulation resistance of Interior Wiring, showing polarity, or "valve," effect (Ohmmeter test).

A, with wires positive, earth negative.
B, with wires negative, earth positive.

use, it is clearly necessary to know something about the individual behaviour of different insulating materials. For this purpose a brief outline will be given of the prolonged experiments that were made on a large number of materials which are in common use for insulating purposes. The materials included rubber, gutta-percha, micanite, porcelain, cotton, paper, silk, oils, and varnishes. Not a title of the work done can be recorded here, but it will be sufficient to describe a few of the more important experiments made on insulators which are typical of their class.

4. DIELECTRIC RESISTANCE.

Our object being to learn something about conduction through moisture, any dielectric leakage there may be through the substance of the insulators can only be ignored if we first show that dielectric resistance is enormous in comparison with the resistance of the leakage paths which are formed by traces of moisture.

the charging current will be V/r micro-amperes. The charging current dies away, rapidly at first then more and more slowly. Ultimately, possibly after many hours, it will have fallen to a value which cannot be distinguished from zero, and the only appreciable current passing through the galvanometer will be the true dielectric leakage, namely $V(R+r)=1$. Since R is always very large compared with r the latter may be

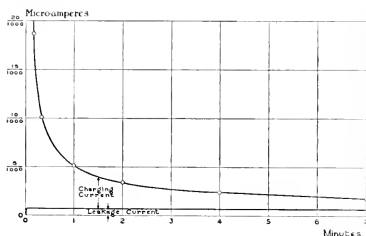

FIG. 8.—Leakage current plus charging current flowing into a rubber cable, from 0 up to 7 minutes.

neglected and $V.I$ will correctly express the dielectric resistance at voltage V —provided the patience of the observer has not been exhausted before the final subsidence of the charging current to zero. The actual result of a test of this kind, made after the flexible had been in the water for 10 days, is shown in Figs. 8 and 9. In Fig. 8 the time-current curve is given from 10 seconds up to 7 minutes after the closing of the charging circuit; while Fig. 9 shows the same curve from 3 minutes up to 420 minutes (7 hours).

Incidentally these two diagrams afford a good illustration of the misleading appearance of curves of this class. Judging from Fig. 8, one would infer that within 4 or 5 minutes the current was already nearly approaching its final steady value: "Well round the bend of the curve" is a phrase often used in this connection. But we have only to change the time scale from minutes into hours, and magnify the current scale by a substantial amount, and the curve conveys a very different impression. Looking at Fig. 9, and again judging by eye, we now draw the inference that instead of a few minutes an hour or more must elapse before the current can be said to be "well round the bend of the curve."

The charge was continued for 27 hours without a break, and by that time the current had fallen to 0.00072 micro-amperes at 525 volts. This was assumed to be the true dielectric leakage current and its value is indicated on each of the diagrams by a horizontal line, in order that the relative magnitudes of charging current and leakage current may be seen at a glance.

It has been the custom ever since the early days of submarine telegraphy to observe the total current at the end of the first minute, and to call the ratio of the charging voltage to that current "the insulation resistance after one minute's electrification," a custom which is still adhered to by cable-makers. Inspection of the curve in Fig. 8 shows

that at one minute 86 per cent of the total current was charging current, only 14 per cent being true leakage current. Hence when a cable-maker specifies the resistance of cable similar to this as so many megohms, his statement only contains 14 per cent of the whole truth. Economy of truth, however, is on the side of honesty in this instance, and the buyer is doubtless aware of the customary method and sometimes understands what it implies.

In this paper we are more concerned with fact than custom. Fig. 8 shows that at one minute the total current was 0.0051 micro-amperes at 525 volts, hence the value of what may be called the "customary resistance" was $525/0.0051 = 103,000$ "megohms" for $\frac{1}{16}$ th of a mile of cable; and the customary resistance of one mile of similar cable would be $103,000/16$, or roughly 6,000 "megohms." The final value of the current being 0.00072 micro-amperes, the real dielectric resistance was $525/0.00072 = 730,000$ megohms for $\frac{1}{16}$ th of a mile, equivalent to a dielectric resistance of 45,000 megohms for one mile of similar cable.

With these figures as a guide let us ascertain the relative importance of dielectric leakage and moisture leakage in some installation of interior wiring in which rubber insulated wires are used. The circuits which gave the characteristic curve shown in Fig. 7 afford a good example, being carried out with rubber-covered wire insulated to the same standard as the flexible we have just examined. The conductors also are of the same diameter in the two cases. The installation contains 380 yards of wire, coupled up in the usual way to a number of fittings in which porcelain is used exclusively as the insulator. Assuming the covering

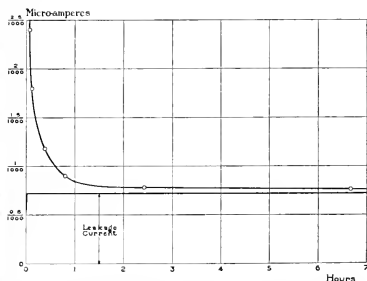

FIG. 9.—Leakage current plus charging current flowing into a rubber cable: continuation of the time-current curve in Fig. 8, up to 7 hours.

of the wires to be undamaged, the dielectric resistance of 380 yards of wire to earth will be about $45,000 \times \frac{177.6}{380} = 200,000$ megohms, and the customary resistance would be about $6,000 \times \frac{177.6}{380} = 28,000$ "megohms." We need not attempt to decide which of these values is to be taken, because it is only necessary to look at Fig. 7 to find that the resistance of the installation as a whole was but a paltry 6 megohms, even when tested in dry weather. The relative importance is now obvious; leakage through the

dielectric rubber is nothing, leakage at the fittings is everything.*

What has been demonstrated in the case of rubber must be equally true with regard to any insulator which has a resistance in any degree comparable with that of good rubber. The resistance of such materials as ebonite, sulphur, glass, mica, gutta-percha, shellac, dry paper, and dry cotton, is in every case enormous; like rubber their specific resistance is measured by millions of megohms, and in most cases by thousands of millions. Hence dielectric leakage will be ignored in what follows. In a later section the conduction through a porous insulator is compared with the quantity of absorbed water it contained an experiment which incidentally gave another convincing proof of the relative insignificance of dielectric leakage.

5. MOISTURE CURVES.

Cotton.—Although this material is so largely used as an insulator for wires the opportunity for observing its

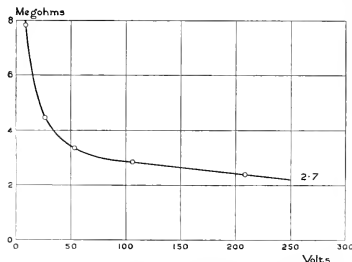

FIG. 10.—Insulation resistance of Cotton which contained a normal quantity of moisture.

resistance seldom or never arises in practice. Several test-pieces were therefore made up for the purpose, each consisting of two cotton-covered wires wound side by side in a single layer on a well glazed porcelain bobbin so that leakage from one wire to the other could only take place through the cotton coverings. One of these cotton test-pieces when tested for insulation resistance from one wire to the other gave the curve shown in Fig. 10. After being dried in an oven at 150° C. for a couple of hours, and then allowed to cool, this test-piece gave the curve shown in

* It may be remarked in passing that the average resistance per leakage point is a useful criterion for the insulation of wiring. In the case of the resistance from wires to earth, the switches, fuse-blocks, ceiling roses, lampholders (if they can leak to earth), and other places where the conductors are fastened to leaky insulators, constitute the leakage points. For resistance between the wires with the switches closed and the lamps removed, the lampholders alone are to be counted; and for resistance between the wires with the lamps in place and the switches open, the switches are the only leakage points that count.

In the example considered in the text the resistance to earth was about 6 megohms, and there were 62 leakage points, hence the average resistance per leakage point was $6 \times 62 = 372$ megohms. Remembering that one switch base of good quality may have a resistance as low as 100 megohms, it is evident that the installation as a whole was in excellent condition as regards insulation.

Rules based solely upon the number of lamps are frequently too remote from the facts to afford much guidance.

Figs. 11 and 12. The resistance is now five or six times greater as the result of the partial evaporation of the moisture originally contained in the cotton, but the general character of the voltage-resistance curve is unaltered. It will be noticed that at 500 volts the resistance has fallen to

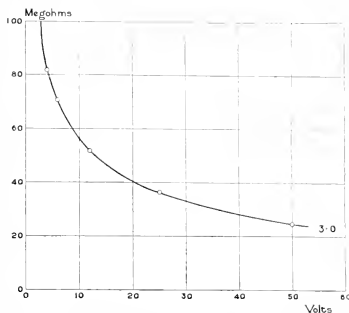

FIG. 11.—Insulation resistance of Cotton; the same test-piece as in Fig. 10, but partially dried by baking.

about one-third the value it had at 50 volts, or to put it shortly $R_{50}/R_{500} = 3$. This is a rough-and-ready way of comparing curves which, although following similar laws, look very different to the eye simply because they are plotted to different scales. In the diagrams the value of the ratio R/R_{50} is marked at the end of each characteristic curve so that different curves may be readily compared, and it will be found as we proceed that in the case of absorbent materials this ratio is more commonly nearer 2 than 3. After further drying at 150° C. for some hours, this

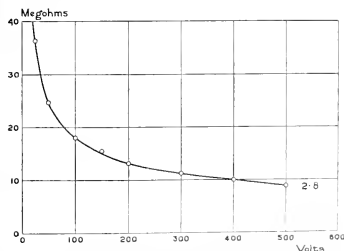

FIG. 12.—Insulation resistance of Cotton; continuation of the curve in Fig. 11 up to 500 volts.

same test-piece gave the curve shown in Fig. 13. The effect of the drying process has been to increase the resistance to something like 80 times the initial value, but

* The exact value of the ratio is 2.8 in this example.

notwithstanding the great diminution in the quantity of water in the cotton, the curve retains the characteristic shape. The reason for this remarkable persistence in the law of moisture conduction under widely varying conditions will be found in a later section.

Paper.—Although cotton exhibits all the phenomena of conduction by moisture, it is not the most convenient material for experiment. Paper lends itself very much

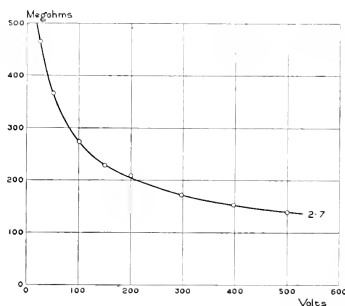

FIG. 13.—Insulation resistance of Cotton; the same test-piece as in Figs. 10, 11, and 12, after further baking.

better to exact conditions as regards the area and length of the insulator interposed between the two conductors. Various kinds of paper under a variety of conditions as regards moisture, compression, length, and area, were

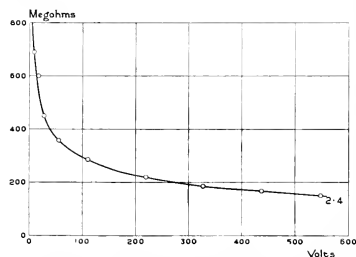

FIG. 14.—Insulation resistance of Paper partially dried and tested at a compression of 2.8 lb. per sq. inch.

exhaustively tested. The test-pieces were each composed of several sheets of paper cut to a suitable size and shape and laid in a pile on a flat copper plate which served as one electrode. A second copper plate on the top of the pile of paper acted as the other electrode, and by putting the complete test-piece in a small screw press any compression could be obtained, from that due to the weight of the upper electrode to about 100 lb. per square inch. As might

be expected, paper behaves in much the same way as cotton. The two curves shown in Figs. 14 and 15 were obtained from drawing paper of good quality. In both cases the paper was in a normal state as regards moisture.

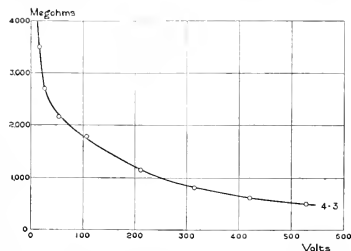

FIG. 15.—Insulation resistance of Paper; the same test-piece as in Fig. 14, but tested at 0.1 lb. per sq. inch.

The law of the characteristic curve is considerably affected by the degree of compression to which the absorbent material is subjected. The curve in Fig. 14 corresponds with a pressure of 2.8 lb. per square inch, whereas in the case of Fig. 15 the pressure was only 0.1 lb. per square inch. The corresponding values of the ratio R_{50}/R_{500} were 2.4 and 4.3. The latter figure is abnormally high and nothing approaching it has been observed in any tests of insulation under working conditions, probably because in practice absorbent insulators are always under a greater mechanical pressure. In Fig. 16 the connection between compression and the ratio R_{50}/R_{500} is traced from zero up to 40 lb. per square inch.

The degree of moisture in an absorbent material, like paper, may be varied within wide limits without much

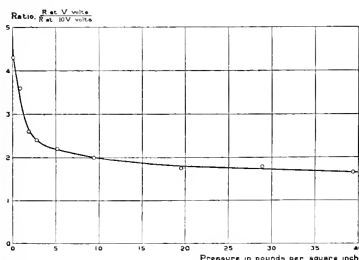

FIG. 16.—Influence of compression on the shape of the "moisture curve" of Paper and similar insulating materials.

affecting the law of the moisture curve, although the corresponding variations in the resistance will be enormous. But when the material contains a considerable excess of moisture, so that it is sensibly damp, the law

begins to change; the ratio R_1/R_2 gradually approaching unity as a limit and the curve subsiding into a horizontal straight line. In other words when an absorbent insulator

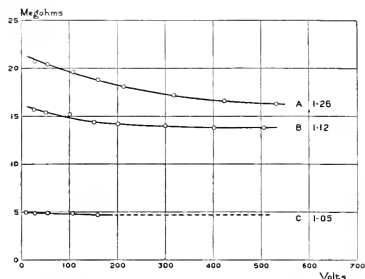

FIG. 17.—Moisture curves of damp Paper showing gradual change from moisture conduction to Ohm's law as the Paper becomes sodden with water.

is sodden with water its resistance follows Ohm's law. This gradual change from a moisture curve is illustrated in Fig. 17, the curves being obtained from paper in which increasing quantities of water had been absorbed. Owing to the very low resistance of the wet paper, curve C could not be continued beyond about 160 volts.

Micanite Cloth.—The test-pieces for examining this material were made up by wrapping a single thickness of the cloth round a piece of smooth iron pipe, and then winding a single layer of cotton-covered wire tightly over it. The cloth was therefore tested under much the same

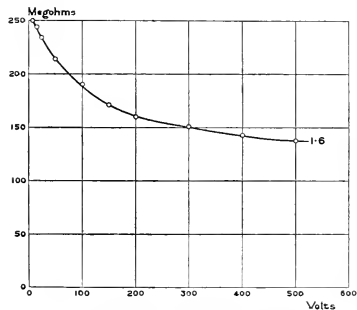

FIG. 18.—Insulation resistance of Micanite Cloth which contained moisture absorbed from the air.

conditions as are commonly met with in practice, micanite cloth being largely used as an insulator for windings. Of course in ordinary use there may be leakage over the

surface of the cloth in addition to that which takes place through the insulating material; but as it was intended in these experiments to investigate conduction *through* the micanite apart from any other leakage, guard wires were tightly twisted round the cloth which projected beyond the winding at each end of the test-piece.

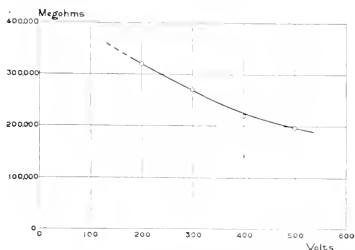

FIG. 19.—The same test-piece as in Fig. 18 tested 24 hours after being dried in an oven. *Note:* One hour after removal from the oven this test-piece had a resistance of 1,300,000 megohms at 500 volts.

One of these test-pieces, immediately after being wound and before being dried, gave the curve shown in Fig. 18. Notwithstanding the presence of the layer of mica the curve indicates conduction by moisture. The rather low

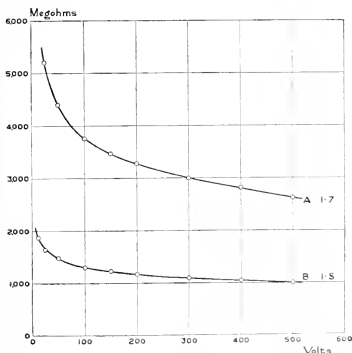

FIG. 20.—The same test-piece as in Figs. 18 and 19, tested after exposure to the air for (A) 5 days, and (B) 90 days.

resistance suggested that there was a good deal of water absorbed in the cloth, and the test-piece was therefore baked for about four hours at 150°C . In one hour after removal from the oven the test-piece was cold and its resistance was then about 1,300,000 megohms when tested at 500 volts. It was then left exposed to the air of the

experimental room in order to find out to what extent micanite cloth acted as an absorbent of atmospheric moisture. At the end of 24 hours' exposure the curve reproduced in Fig. 19 was obtained, showing that the resistance had fallen, although it was still barely within the range of easy measurement. The two curves given in Fig. 20 were obtained after exposure to the air for 5 days and 90 days respectively.

It is by no means surprising to find a laminated substance like mica acting as an absorbent body, and in the form which it necessarily takes in micanite cloth there are innumerable capillary spaces available for the formation of leakage paths. It should be noticed that in these curves the ratio R_{90}/R_{50} is much less than 2; the average value deduced from seven curves obtained from micanite cloth test-pieces is 1.47.

Many other more or less absorbent insulators might be added, but the three examples which have just been examined are typical of the whole. The composition of the insulating substance seems to be of little importance. So long as the structure of the material is such as to provide capillary spaces to harbour moisture, leakage will take place in the characteristic manner. Of course the difficulty of maintaining adequate resistance in absorbent insulators is fully realized, and they are seldom used without an attempt being made to exclude moisture by means of some non-absorbent insulator applied as an oil or a varnish and intended to close all the capillary channels. In the following sections the effect of filling up the pores of absorbent materials is dealt with in connection with oiled paper and varnished windings.

6. CONDUCTION THROUGH OIL.

Oils are good insulators in themselves, but they are capable of absorbing traces of water. An investigation was therefore made to ascertain whether water when absorbed in oil behaved in the same way as moisture in an absorbent solid. For the purpose of the test a glass beaker was fitted up with two flat copper discs, one above the other, to act as electrodes. The upper disc was adjustable up and down by a micrometer screw so that the electrodes could be set accurately to any required distance. Several different kinds of oils and varnishes (and also liquids which are used as solvents in varnishes) were tested in this apparatus and in every case Ohm's law was followed, the resistance proving to be a constant quantity not varying with the potential difference between the electrodes. It was necessary to know whether the same thing applied to oil in which water had been absorbed. The oil used for the test was a heavy hydrocarbon sold as a lubricant for gas engine cylinders. It had the disadvantage of a rather low resistance—about 2.5 million megohms for a centimetre cube—but it was chosen because a large store of it was available, and hence uniform samples might be relied on. A trace of distilled water was dissolved in the oil by putting a few drops into a bottle containing a pint of oil and stirring for many hours. The oil was then left at rest for about 48 hours in order to allow the sus-

pended water to settle down. The slightest trace of water in suspension is apt to cause instability in the resistance because all the suspended particles are slowly drawn in between the electrodes by the electrostatic force, and when there they tend to form conducting chains from one electrode to the other. The result of a test with oil containing absorbed water is shown in

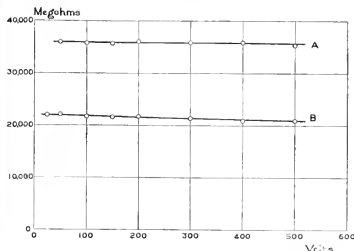

FIG. 21.—Resistance of Cylinder Oil: A, when dry; B, containing a trace of absorbed water.

Fig. 21, the upper curve being obtained from cylinder oil freshly drawn from the storage tank and the lower curve from the same oil after absorbing water. Notwithstanding some irregularity due to water in suspension, the effect of the absorbed water is evident in the marked lowering of the resistance. But of any effect like that due to moisture in absorbent solids there is no trace. In both curves the resistance is practically constant, Ohm's law being followed well enough.

7. OIL-IMPREGNATED PAPER.

Paper containing moisture may be saturated with an insulating oil without producing any effect on the leakage paths by the water. The curve shown in Fig. 22 was obtained from drawing paper which, while in a

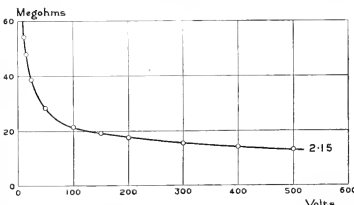

FIG. 22.—Insulation resistance of Paper which had been soaked in dry Cylinder Oil for a week.

normal state as regards moisture, was immersed in dry cylinder oil and left to soak for a week before being taken out and tested. The resulting curve does not differ in any way from an ordinary moisture curve, the ratio R_{90}/R_{50}

* The oil used for impregnating paper cables has a specific resistance of about 200 million megohms, at 15° C.

† The water may not be in solution in a chemical sense, but it is permanently absorbed in the oil, whereas any water in suspension or forming an emulsion with the oil, ultimately separates out and falls to the bottom of the vessel.

being 2:1 for the oiled paper. It is evident that the oil does not displace the water, or break up the conducting paths, or interfere in any material way with the characteristic conduction due to the moisture which was present in the paper before the entrance of the oil.

The converse, however, does not hold good. Water will not only find its way into paper which has been dried and soaked in oil, but will so far displace the oil as to form leakage paths. As is well known, paper impregnated with oil easily absorbs water from the air. Hence the necessity for the lead covering and soldered joints of an impregnated-paper cable. To ascertain whether moisture absorbed by an impregnated paper cable was able to form leakage paths of the same kind as those in other absorbent solid materials, a short piece of lead-covered impregnated-paper cable was left with both ends open and exposed to the air of the experimental room. The curve shown in Fig. 23 was obtained when the cable had been open to the air

very slowly absorbed afterwards, but once inside it will conduct electricity just as though the oil was not there.

8. VARNISHED WINDINGS.

Varnish is intended to prevent water from forming leakage paths. To do this it must either keep out water by closing all the pores at the external surface of the insulator, or it must interpose a solid and impervious layer of the body of the varnish between the conductors and the porous insulator. Applying varnish by a brush aims at the first alternative, vacuum methods aim at the second. It need hardly be pointed out that when a porous body is saturated with a liquid varnish, and the solvent is then dried out, the solid body of the varnish remaining in the insulator is necessarily insufficient in quantity to fill up the pores. They can only be entirely filled up by soaking the insulator in oil, or in a melted wax or in some equivalent solid insulator which can be liquefied by heat. Hence a porous insulator, even when varnished, is likely to have many channels available for the reception of water. Whether water can find its way into them depends on how far the varnish has been able to stop up the pores on the outside of the insulator.

Experiments on varnished windings occupied many months, and in several cases varnished test-pieces have been kept under observation for over two years. Their outcome can be summed up in a sentence. Varnish reduces the extent to which moisture is absorbed, but it seems powerless to stop absorption altogether if the windings are subjected to the temperature variations which occur in ordinary use. This failure to exclude moisture was exhibited in every trial, both by test-pieces varnished by a vacuum method and by those which had received coats of varnish applied by a brush. A couple of tests will illustrate the whole series.

The vacuum method consisted in first baking the test-piece at 150°C . for several hours; then putting it into the vacuum chamber and exhausting down to a few mms. pressure; then running in the varnish until the test-piece was completely submerged, the vacuum pump being kept going and the varnish boiling for half an hour or so. Next, air was admitted to the vacuum chamber and the test-piece was left under atmospheric pressure for an hour or more in order to give ample time for the varnish to be forced into the insulation. After this the test-piece was baked for several days at a temperature not exceeding 150°C ., and after cooling, the resistance tests were begun. One of the test-pieces, composed of two cotton-covered wires wound on a porcelain bobbin, had an initial resistance of 34,000 megohms after being varnished by this method with a black plastic varnish of good quality. The resistance followed Ohm's law, being constant at all pressures up to 500 volts, thus indicating conduction by the varnish and the absence of moisture conduction. Yet after exposure to the air of the experimental room for 9 days this test-piece gave a perfectly normal moisture curve with a ratio R_0/R_{500} equal to 2:1, and the resistance had already fallen to less than one-fourth of the initial value. This fall in resistance and change in the law of conduction are shown in the two curves in Fig. 24. The resistance continued falling for several months and ultimately settled down round about 2 or 3 megohms, rising and falling with the changes in the humidity of the air. A striking experi-

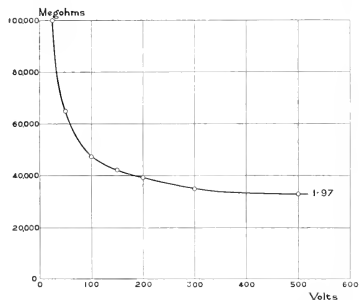

FIG. 23.—Insulation resistance of Oil-impregnated Paper Cable with the ends open, after exposure to the air of the Experimental Room for 13 months.

for 13 months. There is nothing to distinguish it from the characteristic curves of more ordinary absorbent insulators. The ratio R_0/R_{500} is 1.97, quite a normal value for a moisture curve when the absorbent material is under a moderate compression.

Although water ultimately finds its way into impregnated paper, the process of absorption is extraordinarily slow. The piece of paper cable when first tested had a resistance of about one million megohms at 500 volts, and although this high value was not maintained for more than a month or so, it required nearly 9,000 hours' exposure to the air to reduce the resistance to 33,000 megohms. Had the cable been insulated with dry paper (not impregnated) the resistance would have fallen to the same extent—in other words, the same quantity of water would have been absorbed—in four or five hours at the most.

The experiments on oiled paper lead irresistibly to the conclusion that the mode in which absorbed water forms conducting paths is substantially the same whether the insulator is saturated with oil or not. The water may be in the insulator before impregnation with oil or it may be

ment was made on this test-piece by boiling some water in an open vessel in a room adjoining the experimental room. Upon opening the communicating door so as to admit air laden with water vapour, the resistance of the test-piece immediately began falling and continued doing so for half an hour. At the end of this interval the boiling

but the varnish has in this case greatly reduced the amount of moisture which the insulation can absorb.

There can be little doubt that the failure to exclude moisture altogether is due to insufficient elasticity in the body of the varnish. Unless this is a highly elastic substance it is unable to follow the expansions and contractions of the windings, and ultimately the continuity of the coat of varnish is broken up, leaving numerous crevices by which moisture can enter.

9. VOLUME OF WATER IN THE LEAKAGE CHANNELS.

The first stages in the investigation of any phenomena are necessarily qualitative. Arithmetical quantity only comes when an attempt is made to fit the phenomena into some kind of ordered scheme. It is difficult to apply arithmetic to so elusive a quantity as the resistance of absorbed moisture, but at this point questions naturally arise as to the volume of water which is utilized in forming leakage paths, and what sort of relation that volume bears to the total volume of water in the absorbent insulator.

To find some answer to these questions experiments were made on the resistance of an absorbent insulator containing known quantities of water of a measured specific resistance. The insulator was composed of a number of circular discs of chemically pure filter paper, 12.5 cm. in diameter, piled up into a pad and moderately compressed between two flat metal electrodes. The pad of paper had an area of 122 sq. cm., and its thickness (under the compression) was 0.33 cm., so that the pad occupied a volume of 64.8 cubic centimetres. The specific resistance of the water used in this experiment was 2,500 ohms.

To begin with, a quantity of the water was put into the

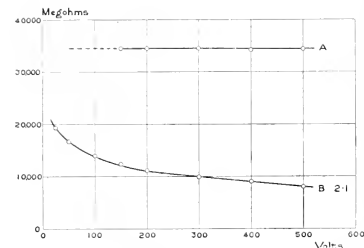

FIG. 24.—Insulation resistance of varnished Cotton: (A) 12 hours and (B) 9 days after baking. Showing the change from Ohm's law (when the test-piece was dry) to moisture conduction after a few days' exposure to the air.

water was removed and the windows of the experimental room were opened in order to restore the air to its original state. Within 3 minutes the fall ceased and the resistance began rising as steadily as it had fallen, until, in about 30 minutes from the time when the boiling water was removed, it had recovered its initial value. One could not have clearer evidence of the ease with which moisture is absorbed by a well-varnished winding.

The history of this test-piece affords a direct proof that the characteristic shape of the first part of the voltage-resistance curve is the result of leakage through moisture. In its initial state, when all moisture had been expelled by prolonged baking, we have a high resistance, and what little leakage there is follows Ohm's law because the varnish itself conducts in that way. But a few days' exposure to the air is sufficient to bring about a complete change in the mode of conduction, and in place of Ohm's law we have the characteristic curve which is common to all absorbent insulators. Finally, we see the resistance falling when the air is artificially charged with water vapour, and rising when the air is restored to its normal condition.

The other test to be described was made on one of the windings used for testing micanite cloth. Two coats of the plastic varnish were applied by a brush to the outside of the winding, and the test-piece was then baked at 150° C. for 32 hours, by which time the varnish was quite dry. After allowing the test-piece to cool, the resistance from the winding through the micanite cloth to the iron core was about a million megohms. This high value was not maintained for long. Within 20 days after removal from the oven a decrease was noticeable, and by the 74th day the resistance had fallen to 33,000 megohms. The curve obtained on that day is given in Fig. 25. It should be compared with the curves given in Fig. 20 for a similar micanite cloth test-piece which had not been varnished. Both curves indicate leakage through moisture,

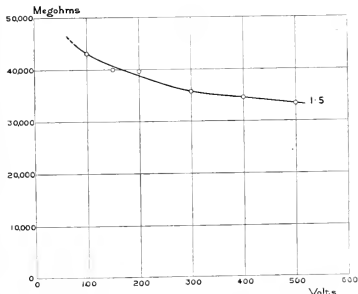

FIG. 25.—Insulation resistance of varnished Micanite Cloth (compare with Fig. 20).

paper and left to distribute itself uniformly. The method of experiment was to measure the resistance of the pad and weigh it immediately afterwards. Next, to allow some of the water to evaporate and then to repeat the resistance test and the weighing. Proceeding slowly step by step, the water was finally dried out and the net weight of the dry

paper ascertained. In this way a number of corresponding values were obtained for weight of water in the paper and resistance of the pad. The figures are given in Table I, the volume of water in cubic centimetres being taken as equal to the weight in grammes.

TABLE I.

Test-point	Volume of Water in the Pad of Paper c.c.	Resistance of the Pad at 500 volts (megohms)	Estimated Volume of Resistance Water c.c.	Ratio of Resistance Water to Total Water, expressed in Parts per million	Percentage Volume of Water in the Pad of Paper
A	1.68	93	188×10^{-6}	112	2.59

Remembering that the resistance of a centimetre-cube of the water was only 2,500 ohms, it is obvious by inspection of the figures in the second and third columns that the resistance of the pad is out of all proportion to the volume of water it contains. Let us analyse one of the tests and see how the two things may be reconciled. Test H is a convenient example, because there happened to be exactly 1 cubic centimetre of water in the paper. The problem is to utilize that volume in such a way as to give the water as a whole a resistance of 1,870 megohms. We must begin by using some of it to make a conducting path of the required resistance and of sufficient length to go from one electrode to the other by a rather tortuous route; tortuous, because it must thread its way through a maze of capillary channels in the paper. Having formed the necessary resistance channels we may dispose of the rest of the cubic centimetre of water by storing it inside the paper as an entirely detached body or bodies, so that it can play no part as a conductor. By these arbitrary proceedings the water will have been divided into two very unequal portions, which may be called *resistance water* and *dormant water*.

Still dealing with Test H how much resistance water will be required to make up the observed value of 1,870 megohms? To answer this question some reasonable guess must be made at the length of the tortuous current path. Now the current will certainly take the shortest available route, and there are such an enormous number of intercommunicating channels in the paper that the average length of all the available paths is unlikely to

be more than two or three times the distance between the electrodes. It would require a highly artificial arrangement of the fibres in the paper to compel the current to travel anything like ten times the shortest distance, and in the following calculation it will be assumed that the average path is five times the distance between the electrodes. The electrodes being separated by the thickness of the pad of paper—namely 0.53 cm.—the assumed average length of current paths will be 2.65 cm.*

The volume of a conductor of given resistance length and specific resistance is $\rho l/R$ so that at test-point H we have—

$$\text{Volume of resistance water} = \frac{2500 \times 2.65^2}{1870 \times 10^6} = \frac{0.4}{10^6} \text{ c.c.}$$

Compare this volume with the total quantity of water in the paper, namely 1 c.c., and we arrive at the figure given in the fifth column of the table:—Under the conditions at Test H the proportion of resistance water to total water was only 0.4 parts in a million.

The reader will distinguish between the observed quantities recorded in the table and the figures which are the result of calculation based on certain assumptions, tacit and otherwise. Thus, the average length of the leakage paths has been assumed to be five times the distance between the electrodes; the dormant water has been assumed to occupy blind alleys entirely off the paths of the leakage current; and the conductivity of the water in the pad of paper has been assumed to remain constant notwithstanding evaporation. Let us see in what direction these assumptions affect the magnitude of the estimated volumes given in the table.

First as regards length. Since the volume of a conductor of given resistance is directly proportional to the square of its length, it is obvious that any underestimate in the length of the leakage path will result in an underestimated volume; and if we choose to double the assumed length, then the volume figures must be multiplied by 4.

Now as to the disposal of the dormant water. In Test H, the calculated volume of resistance water was $0.4/10^6$ c.c., and the length of path 2.65 cm. Translated into more familiar units the resistance water in the innumerable leakage channels was equivalent in the aggregate to a single thread of water rather over an inch in length, and a little more than three-quarters of a mil in diameter.† Let us take some of the dormant water and distribute it along this thread in the form of detached drops, like dew on a spider's web. Each drop, owing to its comparatively large volume, short-circuits the portion of thread to which it clings. To fix our ideas, we can suppose the drops occupy half the entire length of thread and therefore reduce the resistance to one-half. To bring up the resistance to the observed value it will be necessary to reduce the sectional area of the remainder of the thread by one-half, and that part of the leakage path which remains effective as resistance will now have a volume equal to one-quarter of the value reckoned on the assumption that dormant water might be left out of account. It is clear,

* Let the engineer who has never used a factor of safety cast the first stone at this arithmetic.

† At test-point I, the thread of water, which is the equivalent of all the leakage paths, had been reduced to less than one-quarter of a mil in diameter.

then, that this assumption leads to an overestimate of volume, and if the whole of the dormant water is shunted into sidings or blind alleys the volume of resistance water as calculated from the observed resistance is overestimated to the maximum extent.

The drops of dormant water which we have supposed to be distributed along the path of the leakage current might just as well be collected together to form one or more larger bodies of water. The principle is the same, and all we have to bear in mind is that the length of resistance thread which remains intact will be greater or smaller according to whether we choose to imagine the masses of water to be disposed along the current path or across it. To take an extreme case, if the whole of the dormant water which was present in Test H could be spread over the surface of one electrode it would form a layer $1/122$ cm. in

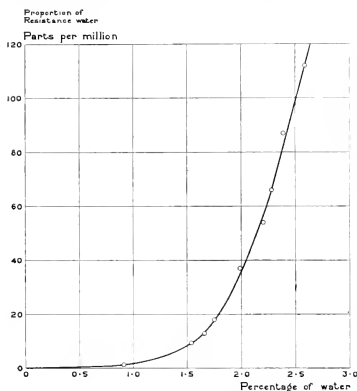

FIG. 26.—Proportion of resistance water to the total quantity of water in a pad of paper (see Table I).

thickness—about $3/2$ mils. The resistance thread (which was about 1 in. long) would therefore be decreased in length by $3/2$ mils, necessitating an equally insignificant decrease in its sectional area in order to maintain the observed resistance of 1,870 megohms. The dormant water would now be wholly in the current path in the form of a very thin sheet, but as its resistance would be much less than 1 ohm we may still regard all the water which is not in the resistance thread as dormant, in the sense that it does not form an appreciable part of the observed resistance.

Finally as regards evaporation: When water evaporates the electrolytic ions generally remain behind, and hence the number of ions in a unit volume of the remaining water increases and the specific resistance falls. But the volume of a conductor of given resistance is directly proportional to the specific resistance, and hence by neglecting the effect of evaporation the volume of resistance water has been again over-estimated.

Taking all these matters into consideration, the figures given in Table I seem rather more likely to be over-estimates of volume than underestimates. At all events they may be accepted as of the right order of magnitude, and the significance of the experiment stands out clearly in spite of some unavoidable guesswork: A vast proportion of the whole volume of water in an absorbent insulator is dormant in the sense just defined. The resistance of the leakage paths through the insulator is determined by an exceedingly small fraction of the absorbed water.

The relation between the volume of resistance water and the total volume is shown as a curve in Fig. 26. The total volume of absorbed water in the paper is here reckoned as a percentage of the volume occupied by the pad of paper.

10. DIELECTRIC CONDUCTION IN DRY PAPER.

Incidentally the weighing experiment affords another example of the relative importance of moisture conduction and dielectric conduction. Referring once more to Table I, we see that when the absorbed water was reduced to a mere unweighable trace, the resistance of the pad of filter paper rose to nearly 12 million megohms, corresponding to a specific resistance of about 2,700 million megohms (cm. cube). This is far below the specific resistance of more thoroughly dried paper, which is certainly not less than 26,000 million megohms. The author is indebted to Mr. Welbourn for this figure; it is a value obtained by the British Insulated and Helsby Cables Company in their test room with carefully dried paper, but even in this case it is doubtful if every trace of water had been removed.

Accepting 26,000 million megohms as at all events a lower limit, it is evident that in Test I moisture conduction was at least 5,000 times greater than dielectric conduction, and in Test A when the pad of paper was much nearer a normal state as regards the quantity of absorbed water, moisture conduction outweighed dielectric conduction more than a million times.

11. THE LAW OF THE MOISTURE CURVE.

The experiments on absorbent insulators suggest that underlying the phenomena there is some ascertainable law of conduction by moisture. The fact, which the wary reader will have perceived already, that it has been possible to compare one curve with another without taking potential gradient in the insulator into account, is sufficient proof that the curves have some simple property in common. And so they have; for in every case in which moisture conduction alone controls the resistance curve, it is found that over a considerable length along the curve the ratio R_2/R_{100} is fairly constant whatever may be the value of τ in volts. Hence although the insulators have varied widely in thickness, the ratio R_2/R_{100} has served quite well as a rough guide for comparing the different curves.

A good example of this property is afforded by the moisture curve for cotton given in Figs. 11 and 12. The fact that in this case a line drawn through the plotted observations forms a smooth curve over a very wide range of potential difference is of itself an indication that disturbances were absent, and hence we are justified in looking here, if anywhere, for a simple law. Table II gives

half a dozen ratios of R_1/R_{100} read off from this curve, and considering the inevitable discrepancies due to instability the figures are remarkably constant and point to a definite law.

TABLE II.

Voltage Points for which Ratio is reckoned	Ratio R_1/R_{100}
5 to 50	3.0
10 " 100	3.1
20 " 200	3.1
30 " 300	2.9
40 " 400	2.8
50 " 500	2.8
Mean value of ratio R_1/R_{100}	2.95

The law would be expressed empirically by the formula—

$$R = k \sqrt[n]{\frac{x}{v}};$$

and since in this particular curve the ratio R_1/R_{100} is only a little less than $\sqrt{10}$, the exponent x must be a number not much greater than 2.

But Nature generally declines the Procrustean bed of formula. Just as in the case of fluid friction she has persistently declined to limit herself either to the first power or to the second power of the velocity (the only alternatives offered to her by the mathematical descendants of Procrustes), so here she refuses to abide by any one exponent. But in each particular case a value may be chosen for x which will express the law of the individual curve over a great part of its length, and hence when the ratio R_1/R_{100} has been found by experiment, the formula may be applied to ascertain any other ratio R_2/R_{100} for values of n lying between 1 and 10. Beyond this modest degree of practical utility the formula is only useful as an indication of the general character of the moisture curve. Further analysis of the characteristic curves may prove useful in suggesting causes for the wide variations from the ideal curve, but in the present stage it is safer to be guided by average results.

12. COMPOUND INSULATION.

If the examples which have come under review in the foregoing pages are divided into two groups according to whether the insulator was composed of absorbent materials alone, or on the other hand built up of some non-absorbent dielectric insulator in series with an absorbent insulator, then their characteristic curves will be found to exhibit a marked difference in curvature, the decrease in resistance being much larger in the first group than in the second. Figs. 2, 22, and 23, are examples of wholly absorbent

insulation, and Figs. 3, 6, 20, and 25, all relate to what may be called compound insulation. In 47 curves obtained from insulation, composed entirely of absorbent materials, such as cotton, paper, cardboard, fibre, and other things, both varnished and unvarnished and including oil-impregnated paper, the average value of the ratio R_1/R_2 was 2.20.

This figure is confirmed by the results of a number of insulation tests on absorbent materials carried out by Mr. E. H. Rayner at the National Physical Laboratory. The materials included presspahn, Manila paper, oiled paper, oiled board, oiled linen, Excelsior paper, Excelsior linen, and fibre, some of them being tested both in their ordinary condition and after varnishing. The insulators were tested under a compression of about 5.8 lb. per sq. in., and a reference to the compression-ratio curve in Fig. 16 shows that the ratio R_1/R_2 might be expected to be about 2.1. But as the resistance of each insulator was tested first at 200 and then at 1,000 volts, the value of R_1/R_2 may be more closely estimated from the observed value of R_{200}/R_{1000} by an application of the empirical formula. Mr. Rayner gives 17 tests within the range of measurement, and taking the whole of these the average ratio R_1/R_2 is 1.71. In arriving at this figure all the readings taken at 200 volts after the application of 1,000 volts have been excluded, as in nearly every case they showed a marked hysteresis effect. Now the formula shows that $\log(R_1/R_{100})$ will be equal to $\log 1.71/\log 5$, and hence we find that in Mr. Rayner's 17 tests the average value of the ratio R_1/R_{100} was 2.15, compared with the author's figure of 2.20 deduced from 47 curves. The figure 2.2 may therefore be regarded as a good average value for the ratio R_1/R_{100} for insulation which is wholly composed of absorbent materials, used under a moderate degree of compression.

But in the case of 12 curves obtained from compound insulation, that is to say insulation in which dielectric-like mica or ebonite were used in series with an absorbent material, the same ratio had an average value of a little less than 1.4. The difference is easily accounted for. The law of moisture conduction in any given absorbent material must be the same, whether there is a dielectric insulator in series with it or not, and assuming the dielectric has a constant resistance the absorbent insulator alone is responsible for the curvature of the resistance line. For an example turn to Fig. 6, which is the characteristic curve obtained from a supply meter in which the absorbent insulation of the windings is in series with the ebonite that serves to insulate the working parts from the case of the instrument. As it stands the ratio is only 1.35, but suppose we draw a new horizontal line at such a distance below the curve as will make the ratio R_2/R_1 , as deduced from measurements from this line to the curve, equal to the average for absorbent materials, namely 2.2. Then ordinates measured from the new datum up to the curve will represent the resistance of the absorbent insulation of the windings, and the distance from the new datum line down to the original base line will represent the resistance of the ebonite.⁶ The height at which to

* Journal I.E.E., vol. 34, p. 924, 1905.

⁶ It may be the resistance of a combination of the surface of the ebonite, for external films have in several cases been found to follow Ohm's law. The point requires further investigation.

draw the new datum is easily found by trial and error, or it may be found at once from the following formula:—

$$\text{Constant part of resistance (total resistance at 500 volts)} \frac{a-n}{a-1}$$

where n is the observed value of the ratio R_2/R_1 , and a is the value of this ratio for the absorbent insulator by itself. In the present example the observed resistance at 500 volts was 1,140 megohms, n was 1.35, and we may take for a the average value 2.20. With these figures the resistance of the ebonite alone is found to be 810 megohms, and a datum line has been drawn in Fig. 6 to represent this value. The only uncertainty here lies in the value we choose for a , the ratio for the absorbent part of the insulation. Now although we have seen how mechanical pressure on the absorbent material may cause this ratio to vary from about 1.7 up to as much as 4.3, yet such wide variations have not been found to occur in practice. Probably absorbent materials are always used under compression, but however that may be, the ratio for absorbent insulators under the ordinary conditions of use does not seem to exceed 2.6, and it is frequently as low as 1.8. If these extreme figures are substituted for 2.2 in the above calculation the resulting values for the resistance of the ebonite will be 800 and 640 megohms respectively, instead of 810 megohms. Such variations as these do not in any way affect the utility of this method by which the two components of an insulation may be separately estimated. In general, if the curve of a compound insulation of the kind we are considering shows a ratio as high as 2 we may be sure that the resistance of the dielectric component has fallen to something approaching zero, either because it has broken down in itself, or because it has been shunted by some kind of absorbent dirt. An example of this happens to be available in Fig. 5. This curve was obtained from an ammeter having absorbent insulation in series with ebonite, yet the ratio is nearly 2 and the resistance is much below the normal value for insulation of the kind.

Upon removing the cover of the instrument the ebonite was found smothered in a mass of fibrous dirt which in the course of a dozen years or so had found its way there through a small hole in the case. Upon removing this highly absorbent shunt and cleaning the ebonite the resistance rose to over one million megohms.

It must be remembered that a non-absorbent dielectric in series is not the only cause of a low ratio value. We have already seen in Fig. 17 how the curve flattens out when there is enough absorbed water to form paths of constant resistance in parallel with those which give a typical moisture curve. But under such circumstances the resistance curve will be so very far below the average level which it occupies under more normal conditions that there is no likelihood of the low ratio that is associated with wet insulation being attributed to the presence of a non-absorbent dielectric in series with the absorbent materials.

The percentage degree of absorption at which leakage paths of constant resistance begin to form inside a porous insulator must naturally vary widely in different cases. Judging from the shape of the curves obtained from paper it would appear that so long as the absorbed water does not exceed the amount which is naturally absorbed from the air, leakage through paths of variable resistance is

paramount and the normal moisture curve will be obtained. How far paper is typical of absorbent insulators in general remains to be seen.

The experiment of weighing the water has already shown us how small a proportion of the absorbed water is actually utilized in forming the leakage paths which determine the resistance of an absorbent insulator. Referring once more to Table I, we see that under quite ordinary conditions the dormant water may easily outweigh the resistance water by at least 10,000 to 1. The exact proportion is of little importance, but when once the principle governing the disposition of absorbed water inside a porous insulator has been grasped, the confusing phenomena of leakage through moisture begin to arrange themselves in some sort of order.

13. ELECTRIC ENDOSMOSE IN A MODEL INSULATOR.

So far the investigation had not suggested any rational explanation of the moisture curve; possibly because the importance of the principle just referred to was not recognized until after the model insulator, which is now to be described, had given a visible demonstration of the cause of the gradual decrease in resistance with increasing potential difference. The explanation given in the following pages was ultimately arrived at, not as the result of previous experiment, but by first considering what was likely to happen when atmospheric moisture condensed inside a porous insulator, and then putting the notion to the test of experiment.

When condensation takes place on the surface of a solid body it first makes its appearance to us in small detached drops clinging to every roughness, every scratch on the surface. If we suppose the solid body to be an insulator of infinite (or at all events immeasurable) resistance, the presence of detached drops of water will not make any appreciable change in that resistance, and the same holds good for the maze of internal surfaces inside a porous insulator when moisture condenses there. But, as we have seen, the absorption of a mere trace of water brings about a vast decrease in resistance; reduces it from an immeasurable value to one easily within the range of our instruments. We cannot suppose the drops to coalesce in order to form a continuous leakage path, because in that case conduction would be simply that of an electrolyte and would follow Ohm's law, leaving the moisture curve unexplained. We must therefore look for connecting links between the drops to establish a complete conducting chain. It would be natural to suppose the links to be films of some kind condensed on the surfaces of the capillary passages in the insulator, and to account for the characteristic curve the films would have to be endowed with a property analogous to that of the electric arc; with increasing electric pressure they must increase their sectional area either by reason of the leakage current they carry, or in consequence of some effect which, like endosmose, depends on the potential gradient. At the time this hypothesis was first outlined it hardly appeared any more likely to contain the germ of truth than half a dozen others that had suggested themselves in the course of research, only to break down on trial. Nevertheless it was put to the test of experiment, and has proved itself capable of accounting for the facts.

To experiment with a series of drops and connecting films deposited on any kind of exposed surface would have

led to almost certain failure, owing to the difficulty of protecting the films against currents of air. This liability is almost non-existent inside a porous insulator, where any considerable change in the humidity of the air occupies a comparatively long time, and the consequent changes in the films and their resistance are not too quick for experiment. To imitate this condition of moderate stability it was decided to construct a model insulator by drawing a series of drops of water and bubbles of air into a capillary glass tube, so that each bubble should constitute an enclosed region within which a film could form on the internal surface of the tube and remain there entirely undisturbed by air currents. Glass was not only an obvi-

ous in the upper part of the same figure. At A and B dark transverse lines, corresponding to "Newton's rings," were seen at the end of each drop where the water-air surface approaches the glass at a capillary angle. These lines formed convenient gauges for estimating the initial thickness of the film of water deposited on the glass, and it was apparent that in the neighbourhood of the capillary edges of the drops the thickness of the film did not exceed one-quarter of the mean wave-length of light.

To understand the behaviour of this tube it is necessary to have the principle of electric endosmose clearly in mind, and as this effect is almost inseparable from electricity and water a short account of it may not be out of place in a paper which is so largely concerned with the passage of a leakage current through moisture.

To begin at the beginning. When an electrically-charged body is placed in an electric field it is attracted one way or the other according to whether the charge it holds is positive or negative, the attractive force being proportional to the potential gradient (volts per centimetre). It does not matter what the attracted body is made of; water will do as well as anything else, and, given the proper conditions as regards voltage gradient and so on, it will move. For instance, water which is lying on an insulator in an electric field will be urged towards the negative side of the field and will flow in that direction if it is free to do so. A little scrap of paper jumping up from the table towards an electrified stick of sealing-wax is a more familiar example of the same action. The electrification of the sealing-wax provides the potential gradient, and the scrap of paper moves upwards if the gradient is steep enough.* Both the scrap of paper and the water move for the same reason, and the only difference lies in the mode by which they receive the necessary charge of electricity. In the case of the scrap of paper the charge is induced by the sealing-wax; whereas the water becomes charged by *contact* with the insulator, just as zinc becomes charged by contact with copper. But although no real difference in principle is involved the action goes by very different names in the two cases. When the scrap of paper jumps we are content to say that it does so because it is attracted, whereas when the water moves because it is similarly attracted the action is called endosmose.

Any liquid would exhibit the phenomena of electric endosmose provided two essential conditions were fulfilled. These are that the liquid must be either electro-positive or negative to the channel which contains it, otherwise there will be no charge and no force; and its specific resistance must be very high, otherwise it will be impossible to maintain a steep potential gradient inside the liquid without overheating by excessive current. Let an attempt be made to propel mercury by endosmose, and a gradient of something like 50 volts per centimetre would be required to overcome friction. But by the time the gradient had reached 2 or 3 volts per centimetre the resulting current flowing in the mercury would have raised it to boiling-point and the experiment could not go on.

Water, and especially pure distilled water (or condensed

* T. A. L. (500 B.C.), to whom we are indebted for the sealing-wax experiment, does not seem to have laid any particular stress on potential gradient as an essential factor.

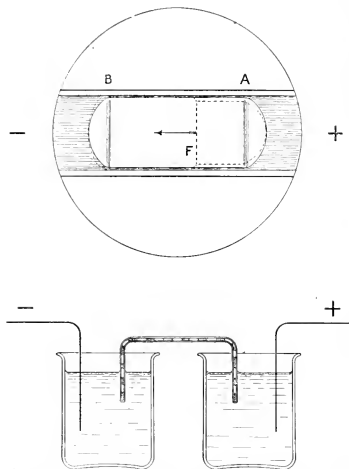

FIG. 27.—Elementary Model of an absorbent insulator. The upper figure represents one of the air bubbles as seen in the field of a microscope.

ously convenient insulating material for the purpose, but as it was intended to look for some visible effect of endosmose a transparent tube was essential.

The glass tube, which was about a couple of inches in length with a bore of 12 or 14 mils, had its ends bent downwards so as to dip into water contained in two small beakers. Before placing the tube in position it was completely filled with a succession of drops of water separated by bubbles of air, the bubbles having an average length equal to four or five times the bore of the tube. Two copper wires, one in each beaker, served as the electrodes. The complete arrangement, as shown in Fig. 27, was fixed under a microscope in such a position that portions of two adjacent drops, with the whole of the air bubble in between them, came within the field of view, as indicated

water), happens to possess both the essential properties in a remarkable degree. It is strongly electro-positive to all insulators (with the one doubtful exception of hair); and its resistance is from 20 million to 2,000 million times greater than that of mercury, so that it is possible to maintain a potential gradient of several hundred volts per centimetre without any overheating by electric current.

Endosmose may be made visible in a short glass tube connecting two water vessels. By contact with the glass the water in the tube acquires a positive charge which occupies a cylindrical layer of water next the wall of the tube, being held there by the corresponding negative charge in the glass surface. When a potential difference of several hundred volts is maintained between the water vessels, the charged water in the tube is strongly attracted towards the negative vessel and moves in that direction down the potential gradient. This movement is confined to the charged layer and such water as it can drag along with it, and when the bore does not much exceed half a millimetre the whole of the water will be set in motion and may be seen travelling slowly towards the negative end of the tube.

Endosmose has been chiefly studied as it appears in glass tubes and in the capillary passages inside porous materials; hence the name, which may be clumsily translated "within-propulsion." But the name must not mislead us. It is not essential to have the water *within* anything; all that is necessary is that the water should be lying in contact with an insulator and forming a conducting path between two electrodes. Then, if the voltage gradient between the electrodes is steep enough, and the water is free to move, it will find its way towards the negative electrode whether there is any definite channel for it to run in or not. But without some kind of trough or tube the water is apt to go by all sorts of devious ways towards its goal, and the confused motion becomes difficult to follow by eye.

To return to the experimental tube with its chain of drops and films. On applying an electromotive force to the electrodes in the two beakers the effect of electric propulsion or endosmose was at once apparent. On closing the circuit the surfaces of the two drops visible in the field of the microscope instantly changed their curvature, the positive surface A pushing its edge out towards the negative side of the field of view, and the negative surface B decreasing its curvature by withdrawing its edge inwards. The dotted lines in Fig. 27 indicate the general nature of this effect, but grossly exaggerate the extent of the change. If the film connecting the two drops happens to be visible^{*} every part of it is seen to experience a sudden force pushing it towards the negative side. The effect of the hydraulic pressure produced in the drops by the electric propulsion is seen at the same time; a stream of water is forced out from the edge of the positive drop and flows rapidly towards the negative drop, increasing the thickness of the film as it goes along. The advancing wave front (F in Fig. 27) of the travelling water is clearly visible, and if the potential difference is gradually increased, the growing thickness of the now moving film is made apparent by its

* The film is only visible when parts of it are thick enough to give some of the colours of Newton's rings. If its thickness is much less than a quarter of a wave-length the film cannot be seen.

assuming, one after another, the colours characteristic of thin films.

The sectional area of the films is of course exceedingly small compared with that of the drops and hence the resistance of a complete tube of given diameter is determined almost entirely by the aggregate length and mean thickness of the films, the resistance of the drops being negligible by comparison. The visible increase in the thickness of the film will therefore be made evident also by a concurrent fall in the resistance of the tube, and if a series of tests be made at gradually increasing potential differences the characteristic curve of the tube as an absorbent insulator may be drawn. In Fig. 28 a curve of this kind has been plotted from tests made on a glass tube about 15 in. long and 135 mils bore, containing water separated by 12 bubbles of air, each of which provided a film length of about 70 mils. The early part of the curve is smooth enough, but the current became increasingly unsteady as the voltage was increased and accurate observation was impossible at the higher readings.

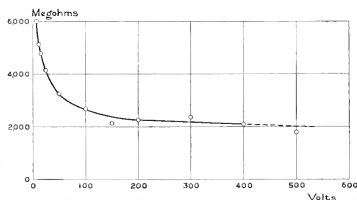

FIG. 28.—Characteristic curve obtained from a capillary glass tube filled with drops of water and bubbles of air, and arranged as shown in Fig. 27.

When the electromotive force is cut off, the surfaces of the drops are instantaneously restored to their normal shape. The surplus water in the films then withdraws very slowly into the adjacent drops, until, after a period which may be hours rather than minutes, the films are reduced to their initial thickness and the resistance of the tube recovers its initial value. The extreme slowness both of the initial formation of the films and their recovery after the application of any considerable potential difference, was not fully realized until the results of all the tests made on tubes were collated some time after the conclusion of the experiments. It then became apparent that the majority of the tests made with single tubes had been carried out before the films had settled down into a normal condition, and their instability naturally led to large discrepancies, particularly at the higher voltages.

But a single tube, one capillary channel, could hardly be expected to give a faithful imitation of a real insulator. Much better results have been obtained from models composed of a number of similar tubes connected in parallel, particularly when they have been given ample time to settle down into a normal condition. The three curves in Fig. 29 were obtained from a model made up of 13 tubes in parallel, curve A being taken 20 hours after filling the tubes, and curves B and C at 44 and 98 hours respectively. In these tests leakage along the external surfaces of the

tubes was eliminated by guarding each tube, and in order to ascertain whether the guard wires upset the uniformity of the potential gradient, a fourth curve D was taken at 113 hours with the guard wires removed. This curve so closely follows curve C that to avoid confusion the mean values of the observations in the two tests have been plotted in Fig. 29 as a single curve representing both C and D.

Reckoning from the average of these four curves the ratio R_0/R_{∞} is 2.1, a figure which agrees surprisingly well with the average ratio 2.2 obtained from absorbent insulators.

Hysteresis, which is such a marked feature of the moisture curves of real insulators, is equally characteristic of the model. In each series of tests upon the model the return curve obtained by retracing the voltage steps from

this too simple model, and the expanding air bubbles lengthen the films and increase the resistance.

But, after all, the structure of the model is not much like the real thing. For the tangled maze of interconnected channels in a porous insulator the model substitutes a number of parallel channels, each going without a break from one electrode to the other; it contains no blind alleys and no cross-connections. Hence in the model the proportion of dormant water falls far below the proportion which we have found by weighing the water in the real insulator. How far below can only be estimated when the thickness of the films is known.

14. THICKNESS OF THE FILMS.

The net resistance of a measured length of film in a glass tube containing drops of water of known conductivity enables the thickness of film to be estimated, on the assumption that it is uniform. Reckoned in this way the films in the tube which gave the curve shown in Fig. 28 had a thickness not exceeding 10 millionths of an inch. The films are of course very far from being uniform in thickness and hence this figure is only a rough estimate.

One of the films in the same tube was measured by the method of Newton's rings, which gave the value 5.5 millionths of an inch.

The two measurements were made at the same time, the films having the maximum thickness corresponding to a potential difference of 500 volts. The two values do not differ more than one would expect, and as the second method is the more accurate we may say that in this tube the thickness of the films was about 6 millionths of an inch when swollen by the action of endosmose. Hence judging by the concurrent decrease of resistance, their initial thickness must have been about 2 millionths of an inch. This is so much less than one-quarter of a wave-length of light that in the initial state the film had no perceptible colour by which to estimate thickness.*

15. DORMANT WATER IN THE MODEL.

We can now estimate the proportion of dormant water to film water in the model. Most of the tubes have been about 2 in. in length, and about half the length has been occupied by films and the other half by water. The bore of the tube being about 14 mils, its perimeter is 44 mils. The initial thickness of the film was $2/10^6$ in. = $2/1,000$ of a mil, and the aggregate length of film was about 1,000 mils. Hence the volume of water in the films was about 88 cubic mils.

The sectional area of the drops is 154 sq. mils, and since they occupied about half the length of the tube their aggregate volume was about 154,000 cubic mils. Hence the ratio of dormant water to film water was $154,000/88 = 1,750$. That is to say for one part of water in the films there are something less than 2,000 parts of dormant water.

Now in a real insulator the corresponding proportion is, as we have seen, much more like 10,000 or even 100,000 to 1; from 5 to 50 times as much. To represent reality in this respect it would be necessary to build up a model with

* The wave-length at the 500 nm line in the spectrum is 25 millionths of an inch. It is worth noting that at its thinnest the film has depth for about 170 molecules.

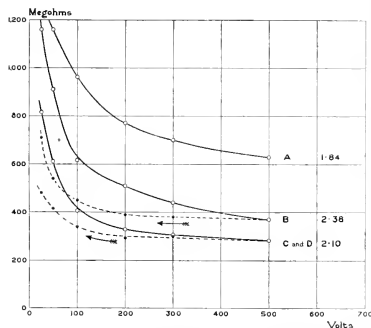

Fig. 29.—Characteristic curves obtained from a Model Insulator composed of 13 capillary glass tubes arranged in parallel.

500 back to 25 volts has indicated a pronounced hysteresis effect. The return curves obtained immediately after curves B, C, and D, have been included in Fig. 29, and should be compared with the examples of hysteresis in real insulators which have been given in Figs. 2 and 5.

The general resemblance of the curves given by glass models to those which are characteristic of absorbent insulators is evident. In the decreasing resistance with increasing voltage, in the extent of the decrease, in the slow recovery or hysteresis, even in instability, the films and drops possess properties which are common to every absorbent insulator. The dormant water which we found in the pad of paper is here in the drops, and the resistance water is visible in the films which link the drops together into a conducting chain, and provide the high resistance.

But in one matter a simple model composed entirely of open tubes differs fundamentally from a porous insulator. The first effect of heating an absorbent insulator is to bring about a very large decrease in resistance. Heat

a very large number of closed tubes in addition to the open or conducting tubes, and to interconnect the two sets, by numbers of cross tubes. When the whole assemblage was filled with water and air it would form one hydraulic system, although electric conduction would still be confined to the open tubes. The whole of the water, both in the open and in the closed tubes, would be attracted towards the negative electrodes, and at every place where there happened to be a convenient junction between a closed tube and an open one, dormant water might be driven out into the latter and assist in swelling the films in the conducting channels.

16. THE PROPERTIES OF A MODEL INSULATOR.

Heat this complex model and the expansion of the trapped air ³ in the closed tubes will drive a large volume of dormant water into the conducting channels. At the same time the expansion of the air in the open tubes may have lengthened or even broken up some of the films, but remembering that the closed tubes may contain perhaps fifty times the volume of air and water, it is evident that the quantity of dormant water forced out from the blind alleys will be enough to flood the conducting channels, quite apart from what may happen to individual films. The flooding of the conducting paths naturally brings about an enormous fall in resistance. Lower the temperature and the air bubbles throughout the system will contract and the flood water will retire into the blind alleys. The films then slowly recover their initial thickness as the surplus water is forced out of them by the tension of the water-air surface, and the resistance rises to its former value.⁴

Another remarkable property of absorbent insulation finds a ready explanation in the model with its tubes full of drops and films. Over and over again in the course of the investigation a number of moisture curves have been obtained under widely different conditions as regards the quantity of absorbed water. Yet the curvature of the characteristic has remained practically unchanged throughout the whole series of tests notwithstanding the enormous changes in the general level of resistance which accompany changes in the amount of absorbed moisture. This permanence in the shape of the curve has already been referred to, and in view of what has been demonstrated by means of a bundle of capillary glass tubes the explanation is clear. Place a damp insulator in a dry atmosphere so that evaporation takes place. Evidently the more accessible films will evaporate first, followed by film after film, and the least accessible and thickest films will be the last to go. But as each film gives more or less the same sort of curve, the curve from a few dozen film channels in parallel would be indistinguishable in shape from the curve obtained when there were hundreds or thousands of films acting as parallel leakage paths. Hence so long as a few film channels are left intact—just enough to carry a measurable leakage current—the resistance-voltage curve will

retain its characteristic shape. We now realize why it was that a piece of impregnated paper cable which had absorbed a trace of water, giving a resistance of several hundred thousand megohms, had a characteristic curve of the same shape as that obtained from a dynamo armature the resistance of which was less than a dozen megohms. The curve is characteristic of the film with its adjacent reservoirs of dormant water; the magnitude of the conductance is simply a question of the number of film paths acting in parallel.

The marvellous rapidity with which the resistance alters when a change occurs in the humidity of the air is of course attributable to the extreme tenuity of the films.

All these phenomena should become visible in a complex glass model if only we had skill to make it. But, after all, the necessary complexity is available in every porous insulator, for there we have a tangled system of innumerable conducting channels, cross connections, and blind alleys, ready made; an elaborate natural system which could not be imitated by any artificial arrangement of a few glass tubes. If we direct our mental vision to the inside of a real absorbent insulator we shall see a bewildering number of channels occupied by films and drops in which the same kind of actions are going on as those which are visible in the glass tube; and mingled with the elaborate hydraulic system there will be a quantity of air, some of it—perhaps a large proportion of it—trapped in blind alleys by plugs of dormant water, and always ready to expand when heated and drive the water out into the conducting channels.

17. SUMMARY AND CONCLUSION.

This vision of what goes on inside an absorbent insulator, misty and imperfect as it is, provides an explanation in general agreement with the facts. In putting it forward the author is conscious of difficulties and obscurities which leave the mind doubtful, but the doubts are just those which come from ignorance of the precise structure of absorbent bodies and the mode in which they harbour moisture. In all probability the microscope would dispel a good deal of this cloud of ignorance if it were applied to some typical material like a thread of cotton.

But the facts which have emerged from the investigation leave no room for doubt as regards the main characteristics of insulation resistance under working conditions.

The true dielectric resistance of insulation is enormous compared with the actual insulation resistance obtained in practice, and in all ordinary cases we need only consider the leakage which takes place through films of moisture condensed on the external and internal surfaces of the insulating material. Dielectric leakage is insignificant and may be left out of account.

The quantity of water in the conducting films of moisture is not only very small, but it forms an exceedingly small proportion of the whole volume of absorbed water.

Impregnating an absorbent insulator with oil or varnish delays the absorption of water and no doubt limits the amount absorbed, but it does not prevent the ultimate formation of the moisture films which constitute leakage paths.

Conduction through absorbent insulation does not follow Ohm's law. The relation between the resistance of an absorbent insulator and the potential difference which is

³ Inside a porous insulator containing a normal amount of moisture the volume of air will vastly exceed the volume of dormant water, and there must be innumerable bubbles of air trapped inside capillary spaces by drops of water.

⁴ The above explanation of the action of heat on absorbent insulation has its origin in a suggestion made by Mr. A. Campbell and embodied by Mr. E. H. Raver in the report on Temperature Experiments at the National Physical Laboratory (*Journal I.E.E.*, vol. 34, p. 624, 1905).

applied to it is expressed by a curve which is characteristic of conduction by films and drops.

When the absorbed water exceeds the amount which the material can hold in the form of dormant water and leakage films it begins to form conducting paths of constant resistance. Hence the moisture curve gradually decreases in curvature as absorption goes on, and ultimately when the resistance has fallen to a very low value the curve is reduced to a horizontal straight line, indicating conduction by Ohm's law.

In compound insulation consisting of an insulator in which conduction follows Ohm's law, in series with an absorbent material which follows the law of moisture conduction, the resultant curve has less than the normal curvature.

The degree of curvature in the characteristic curve of compound insulation enables the resistances of the two components to be separately estimated.

In compound insulation a curve of normal curvature indicates failure of the dielectric component. A straight horizontal "curve" (Ohm's law) indicates failure of the absorbent component.

Finally, the broad principle of film conduction in an absorbent insulator is clear; the moisture curve—the first part of the complete characteristic curve—is the direct result of electric endosmose. The electrically produced hydraulic pressure drives dormant water into the films, and their increasing thickness is made evident by the gradual fall in resistance as the potential difference is increased.

At what point leakage through moisture becomes dangerous; whether the ultimate effect of prolonged endosmose is to safeguard the insulation by driving all the water away from the positive conductor in a continuous-current system, and from both conductors if the supply is by alternating current; whether it is possible to predict the breakdown voltage—these and other questions can only be answered by an investigation of the second part of the characteristic curve. Preparations for this are not yet complete, and so far it has only been possible to extend the curve to the breakdown point in one or two simple cases for which the voltage already available proved sufficient. In these examples the curve began to bend downwards at pressures well below the breakdown value, thus indicating the impending failure without exposing the insulation to the risk of permanent injury. It remains to be seen whether this useful effect is general, or whether, as seems more probable, it is confined to insulating materials in which failure begins along already existing leakage channels. It is a significant fact that in the model insulator breakdown begins in the form of sparking along the films from one drop to another. Questions of this kind go to the very root of the matter. It is customary to account for breakdown by dielectric stress; a blackened hole appears in the insulation and the inference is too hastily drawn that the puncture process was instantaneous and could not have been foreseen by any kind of test. But nothing in Nature, not even an explosion, takes place instantaneously, and the breakdown of an insulator is only sudden to the mind that does not apprehend it.

The time may never come when it is possible, by systematic insulation testing, to forestall breakdown by diagnosis of the disease and removal of the cause. To-day the problem as a whole looks wellnigh insoluble, and

with no visible goal ahead of us we must be content to gain a clearer insight as we go along in more or less the right direction. That road is always open to us and the author hopes that facts recorded in this paper may serve as stepping-stones on the way.

NOTE.—The whole of the experimental work has been carried out at Acton-lane works by Mr. S. F. W. Finnis, to whom the author is greatly indebted for the skill and patience with which the laborious and in many cases difficult experiments were conducted. Not the least among many difficulties was the necessity for carrying on the investigation without interrupting the ordinary work of the Experimental Department of which Mr. Finnis has charge. The author also wishes to thank Mr. B. Welbourn of the British Insulated and Helsby Cables Company for his kindness in providing samples of paper cables and the oil and paper used in their manufacture, together with data relating to the specific resistance of these materials. It is always a pleasant task to make acknowledgment of the help which is so freely given by one member of the Institution to another.

APPENDIX.

INSULATION VALVES.

The effect which polarity has on the resistance of some kinds of insulation has been known from the early days of telegraphy in connection with overhead wires run on earthenware insulators. The same effect is frequently met with in testing the insulation resistance of electric-light wiring. So far as the author is aware it was first traced to porcelain insulators by Mr. Bernard Holt. Writing from Perth, West Australia, to the author's firm, Mr. Holt has described some remarkable instances of valve action which he has come across. A new installation of interior wiring, when tested from one wire to the other with the switches open, gave 1·5 megohms with the testing voltage in one direction and 9 megohms when the polarity was reversed. Another installation gave a similar result and, by elimination, Mr. Holt traced the effect to the switches. One of these when removed from this installation and tested for insulation resistance from one terminal to the other, differed in resistance by several hundreds per cent according to the polarity of the terminals. The switch was of the ordinary tumbler pattern mounted on a china base.

The author has had no difficulty in verifying Mr. Holt's tests in every particular. House wiring, whether tested from wire to wire with the switches open, or from the wires to earth, often shows a valve effect. Porcelain base switches of inferior quality have invariably acted like valves. On the other hand, switches of the best quality in which well glazed china is used gave resistances from about 100 megohms up to several thousand megohms, and it was only when the resistance was well within the range of the ohmmeter used for these tests that a valve action could be detected. It is probably inherent in every earthenware insulator. A number of switches of good quality were found to give 10 megohms or so with the voltage applied in one direction, and over 100 megohms

when the testing leads were reversed, the rise in resistance being practically instantaneous. Apart from the highly insulating glaze, earthenware is something between a rather good conductor and a very poor insulator, but it need hardly be pointed out that if a switch base were covered in every part, including all screw holes, with a good glaze which was entirely free from cracks, the resistance between terminals or from terminals to earth would amount to several thousands or even millions of megohms. Such high values would indicate a needless perfection and are no doubt unattainable in practice, but when we find many china bases of poor quality giving not more than one or two megohms each, even in dry weather, we naturally begin to inquire why some limit should not be set to the discontinuity of the glaze. A resistance of two or three hundred megohms would at least be an indication that the glaze was well applied and reasonably free from cracks.

To ascertain the cause of the valve action, tests were made on a flat block of porcelain of good quality. The resistance being far too great for easy measurement, the glaze was partially removed by grinding in order to approach the condition of an ordinary switch base and at the same time obtain a smooth flat surface. Three small electrodes, A, B, and T (see Fig. 30), were secured to

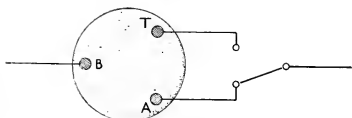

FIG. 30.—Glazed Porcelain Block fitted with three electrodes for investigating the polarity or "valve" effect.

the surface, and the method of experiment was to measure the resistance of the path A B and compare it with that of the path T B, the region round B being common to both paths. Current was never allowed to traverse the path T B for more than two or three seconds at a time—just long enough to allow the ohmmeter reading to be noted—and hence any substantial increase which might be observed in the resistance of this path would be confined to the neighbourhood round electrode B and would be the result of current flowing in the path A B. It was found that when current, flowing in either direction, traversed the path A B the resistance of this path gradually rose until by the time the current had been flowing for half an hour or so the resistance would be twenty or thirty times the initial value. By cutting off the current in A B and immediately taking the resistance of the reference path T B, it was at once seen whether the increase in A B had taken place at electrode B or not. In this way it was proved that when electrode B was positive, practically all the increase in the resistance of A B occurred at or near B; and when that electrode was negative then no material change took place there. That is to say the increase in resistance that results from the leakage current is almost entirely confined to the region round the positive electrode, the conductor where the current enters the earthenware. In one experiment the initial resistance of the path

A B was 40 megohms, and on switching on the testing current, which in this instance entered the porcelain at A, the resistance rose to several thousand megohms in the course of two or three minutes. During this time the reference path T B changed from an initial value of 80 megohms to a final value of 8·2 megohms. Hence of the enormous increase in the resistance of A B only 0·2 megohm occurred in the region near the negative electrode B; practically the whole increase took place in the region of the positive electrode A.

By making both the electrodes very small, the resistance-change may be made to take place almost instantaneously, no matter which way the current flows. If one electrode has a smaller area than the other then the change will take place more quickly when the current enters the china at the small electrode than it does with the current going the other way. By using one very small electrode and one of fair size, the increase is easily made to occur so quickly when the small electrode is positive that it will appear to take place instantaneously, whereas when the electrode of large area is positive the change may take place so slowly that no material alteration will be detected in the time occupied by an ordinary insulation-test. The word "area" is used here in rather extended sense, for it is clear that a metal piece having a large area in contact with the glazed surface might act as an electrode of small area if there happened to be only a few small cracks in the glaze available for the passage of current from the metal into the body of the earthenware. In this connection it would be more precise to refer to access to the interior of the insulator than to area, although the two sometimes mean the same thing.

Access-area is frequently the result of accidental circumstances. The screw holes in a porcelain base are often insufficiently glazed, and hence the fixing screws for the terminal pieces are apt to have rather easy access to the conducting earthenware beneath the glaze. It is a matter of chance which of two screws will have the better access, and although any individual switch may show a marked valve effect simply because one terminal has a better access than the other, yet a complete installation of similar switches may show no such effect, because they are coupled up to the wiring without any regard to valve direction, and the installation could only show a polarity effect if there chanced to be more valves opening one way than the other.

But chance is not always the governing factor. Where there is some systematic difference in access-area, arising out of constructional features and accompanied by a systematic coupling to a circuit, there the circuit as a whole will show the valve effect. An overhead telegraph line is a good example. At every insulator the line wire, and its binding on the well-glazed surface of the insulator, has a far smaller access-area than the fixing bolt embedded inside the earthenware. Such a line will have a higher insulation resistance to earth when the line is made positive than it has when the polarity is reversed. Electric wiring when tested from circuit to earth will show the valve effect for much the same reason.

The increase in resistance at the positive electrode seems to be due to the clogging of the leakage channels, both the cracks in the glaze and the capillary passages in the body of the earthenware, by the products of electrolysis. But

it is significant that the valve effect is almost as great when platinum electrodes are substituted for the usual brass pieces. In this case oxygen alone is produced at the positive electrode, but some chemical change evidently takes place in the region near the electrode because even with platinum the earthenware is observed to become discoloured, and the resistance remains at the increased value for 24 hours or more after cutting off the leakage current. This seems to point to some solid non-conducting substance choking the pores of the insulator. The action of endomose in driving moisture from the positive towards the negative electrode must not be overlooked. If in this way the water were driven out of the cracks in the glaze near the positive electrode, a very large increase in resistance might easily take place. But upon the whole the facts point to clogging by the chemical action accompanying electrolysis, although endomose may play a subordinate part.

An installation of wiring, which when new may have no valve action when tested from wire to wire, will soon acquire it if the supply is by continuous current. In this case the positive side of every porcelain switch base becomes so clogged by the prolonged electrolysis which goes on whenever the switch is open, that a systematic difference in access-area comes about, the positive terminals in contact with the clogged earthenware acting as the electrodes of small access-area.

The insulation valve is thus seen to be closely related to other well-known electrical valves which depend for their action on the two electrodes having widely different freedom of access to an electrolyte. Glazed earthenware seems peculiarly well adapted to produce a valve effect, but no doubt other porous insulators may be found to act in the same way.

As to the question whether the normal resistance or the abnormal is to be taken as correct, the answer must be that both are real, both are effective in preventing leakage. In a continuous current system the higher value is the one which actually governs leakage if the polarity of the system remains unchanged. But in telegraphy this is not always the case, and it is no doubt advisable to carry out insulation

tests on overhead lines with the line wire negative and use the lower resistance value, so obtained, in estimating the signalling capacity of the circuit.

NOTE.—In introducing the paper the author gave an experimental demonstration of the moisture effect by means of a mirror ohmmeter having a scale 30 feet in length and easily visible to a large audience. Measurements of insulation resistance were made at a series of ascending voltage of (1) a dynamo, (2) a varnished winding, (3) the skin of the hand, and (4) a model insulator composed of a bundle of capillary glass tubes filled with water

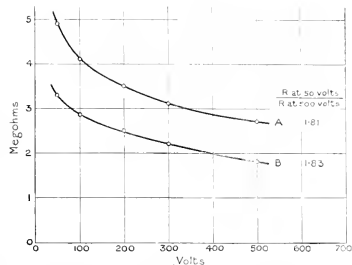

FIG. 31.—Moisture Curves plotted from readings taken in the course of the experimental demonstration at The Institution of Electrical Engineers, on 27th November, 1913.

Curve A: Insulation Resistance of a Dynamo, lent for the experiment by Mr. W. Clark.

Curve B: Resistance of a Model Insulator prepared by Mr. Littlejohn, composed of a bundle of capillary glass tubes.

and bubbles of air. Two moisture curves plotted from the readings so obtained are given in Fig. 31. The readings were noted by Mr. E. B. Vignoles.

DISCUSSION BEFORE THE INSTITUTION ON 27TH NOVEMBER, 1913.

PROFESSOR SILVANUS P. THOMPSON: I think that Mr. Evershed's paper will be, at any rate for some years to come—if not for more than some years—a standard of reference, and we shall look back upon it as a very definite and notable contribution to our knowledge of a very ill-explored but important branch of our science. We have known all too little about the conductance of insulators, and I think we shall be particularly indebted to Mr. Evershed for having directed our attention to what is very rightly called the characteristic curve of insulation resistance. It may be that we shall not always express ourselves in the same terms; it may be that we shall perhaps not always take exactly the ratio of the apparent resistance at 500 volts and at 50 volts; but at any rate, whatever we do in the future, we have now a datum to start from. Mr. Evershed suggests the measured resistances at 50 volts and 500 volts as furnishing a pair of points of reference, with a curve joining them which we can compare as between one substance and another to see

whether they behave alike in their conducting properties; and for that definition, if for nothing else, I think this paper is valuable. It will be our own fault if, having now the means of measuring the insulation resistance in other cases and with other materials, we do not choose to follow the lead that Mr. Evershed has given us, and produce characteristic curves which shall be comparable, in the way in which they are made and plotted, with his. He has laid the foundation, therefore, for a certain definite advance in our knowledge and our means of expressing our knowledge on this subject. When I have said that, I have not said what is perhaps even a greater matter for those of us who have listened to Mr. Evershed: again and again throughout his paper he has given us excellent suggestions, hints, and points to excite our curiosity and our imagination as to what it is that is going on—as to what are the physics of this particular process of the leakage of electricity through the substances which are commonly called insulators. We must all have been impressed, for example,

Professor
Silvanus
Thompson.

with that exceedingly beautiful arrangement of films of water in capillary tubes to imitate by known appliances the behaviour of the water in the pores of solids. When he asked us to think of these porous channels ramifying about in all manner of tortuous directions, having blind ends and holding dormant water which could not take any part in the conductance because it led nowhere, when he gave us this *aperçu*—this vision, as it were—of the interior of a solid, surely we carry away with us a picture in our minds which we can fill up at leisure as more knowledge comes, and we shall be better able to grasp what is going on in materials when we make measurements in the laboratory or in the workshop.

One of the most important points comes out strongly; that is, how very little of the water that is absorbed by an insulator takes any part in the operation. Although it may be that only one-millionth part of the whole of the water is really conducting the leakage current through it—and how difficult it is to stop that millionth!—is it not a most remarkable fact that no chemical substance has yet been found with which to impregnate paper or any of those cellulose materials so as effectively to stop those minute channels? We may parchmentize the material and get rid of its fibre; we may what is termed vulcanize it; we may impregnate with vitriols, oils, fats, and all manner of varnishes, etc.; but we are continually eluded by the water which for ever manages to permeate through the cellulose material. It may be that some day a chemical discovery will be made which will enable us to impregnate paper so that it shall not conduct; but that discovery has yet to be made. How many of us would be glad of a paper product which would insulate, say, as well as ebonite, to say nothing of gutta-percha, or ivory, or amber.

Among the things that come out clearly in this paper, and from what Mr. Evershed calls the instability of the liquid film, is that we do not get a constant insulation resistance or insulation conductance of moisture unless a considerable number of channels are in parallel. The significance of that, if we analyse it, is surely that conductance in a liquid is connected with movement—with the movement of the liquid itself, of the molecules or ions; because such liquids never conduct without being ionized. There is always chemical action in that sense going on, and that means movement. We may have looked in old text-books at the pictures of molecular chains across an electrical cell, and perhaps we have looked in vain for them through our microscopes; yet something very closely akin to this may be seen. If we place on a slip of glass in a microscope a film of a liquid which includes minute particles of, say, gamboge paint (a resin), or minute globules of milk, and examine the liquid when a current is passed through it, we should not see molecular chains, although we shall see small particles; but these are not in rows as represented in text-books. On the contrary we should notice lively movements, chains of twos and threes dodging about. Conductance through a liquid is always a phenomenon of lively movement, and that is going on in these tubes. Unless we can obtain a sufficient number of paths to regularize out the movement in any one chain, then, of course, we get instability. We only get statistically a kind of stability that will permit of steady measurement.

In Fig. 5 Mr. Evershed showed us the decrease of the resistance as the voltage is increased, and how the curve

returns back on itself with what he, in a rash moment, described as a kind of hysteresis. We must be very careful about the use of the word "hysteresis." To my mind, if one wishes to study hysteresis one must pursue a phenomenon right round a cycle. But what would happen if the voltage were repeatedly raised to 500 and reduced to zero? Would a loop be obtained? A zigzagging curve would result until a stable bottom was reached. Mr. Evershed assures me that ultimately a loop is obtained. I am pleased to hear that, because we may be able to calculate something from that loop. I should like Mr. Evershed to deal with that point in his reply.

There is one important criticism I should like to make. I must protest most emphatically against the notion that there are any substances which do not obey Ohm's law. Ohm's law is true under all circumstances for every kind of conductor, or insulator, or current, or anything else. It depends entirely on the definition of "resistance." I do not know any way of ascertaining the resistance of a body except by passing a current through it; the name "resistance" is given to the ratio between the electromotive force that is supplied and the current which results. That is Maxwell's definition. What Mr. Evershed undoubtedly meant, and what those people mean who say that something does not obey Ohm's law, is that the resistance is not constant. When conducting a current the resistance of some substances changes because the molecular condition is being altered. If we think of a liquid carrying a current, and of all the molecular movement that is going on, can we expect the resistance to be constant whether the current is flowing or not? No, the resistance decreases as the current is increased; but Ohm's law is still true, for E/R still equals I . It is sometimes said that Ohm's law is not true if there is a back electromotive force; but so long as we do not disregard the back electromotive force Ohm's law is still true. Some people, again, get the idea that Ohm's law is not true for an alternating current merely because they neglect to insert in the equation the back electromotive force due to the reaction of self-induction. I do not know a single thing that does not obey Ohm's law. Not even in the voltaic arc is Ohm's law violated.

In conclusion, I venture to suggest to the world of electricians that to shorten the phrase "insulation resistance" we should use the term "insulance."

Mr. C. J. BEAVER: While the paper is of more direct interest to makers of electrical machines, instruments, and apparatus than to cable-makers, we are all very much indebted to the author for his collation of facts and the very interesting demonstrations he has made, particularly those with the model insulator. Most of the phenomena referred to in the paper are familiar to cable-makers, who have always recognized the necessity for protecting fibrous insulation by non-absorbent coverings such as lead, and thereby sealing off the insulating material from contact with moisture. They have always recognized that it is impossible to maintain efficient insulation resistance in absorbent dielectrics, however well dried and impregnated these may be originally, unless such seals or barriers against moisture are employed. The absorbency of fibrous materials is due to capillarity, which means a much greater susceptibility to moisture than would be due to other effects such as condensation,

deliquescence, etc. The capillarity of fibrous materials such as those mentioned in the paper is due not only to the structure of the paper or woven fabric as a body, but also to the capillarity of the individual fibres themselves. The sequence of events demonstrated by the characteristic curve for cotton (Fig. 1) corresponds exactly to the cable-makers' experience as to what happens during breakdowns from moisture faults. The osmotic effects illustrated by the first part of the curve merge into the formation of electrolytic products in the dielectric and incipient charring in the second part, passing to final breakdown in the third part of the curve. With regard to the general character of the moisture curves shown for the various kinds of absorbent insulation and moisture films, I would point out that the fall in resistance with increase of testing voltage is simply a matter of the electrodes not making contact with the virtual conductor contained in the non-conducting mass of fibrous material. Imagine a range of materials varying from conductors, through absorbent and therefore imperfect or variable insulators, to non-absorbent insulators. At each end of the range we get a constant relation between resistance and voltage, but in the intermediate materials we apparently do not. The reason obviously is that the conducting component of these materials moves about in the cellular structure; in other words, the insulating and conducting components do not form a homogeneous mixture and are not uniformly distributed, therefore we do not make efficient contact with the conducting component and do not get a conductivity proportional to the resistance of the two components. To take a simple parallel, if we set out to measure the resistance of a stranded conductor, say of aluminium, the strands of which are making bad contact with one another, we should have to connect up every wire of the strand to the test leads before we obtained a true result. The reason for the difference between the curve for oil containing water (Fig. 21) and oil-impregnated paper also containing moisture (Fig. 22) becomes obvious when viewed from this standpoint. In the former we have a homogeneous mixture, and in the latter a collection of substances, the conducting component of which cannot make contact with the test electrode.

The "valve effects" referred to by the author have been well known in cable practice for very many years. It is because of these effects that factory tests on cables are always made with a negative current. In Government and other standard specifications it was customary until a few years ago to specify that cables should be tested with both positive and negative currents, and the results compared. A difference of not more than 5 per cent in the insulation-resistance figures thus obtained rendered the cables liable to rejection. The custom lapsed because in course of time cable manufacture arrived at such a stage of perfection that the test with negative electrification could be solely relied on. The various hysteresis effects noted by the author are probably closely connected with "valve effects." In relation to Fig. 8 the author refers to the real dielectric resistance of cables as compared with what he calls the customary resistance. It may be of general interest to point out that the customary method of testing the insulation resistance of cables by "loss of charge" is the only practical method. The real dielectric resistance is much greater than is indicated by the nominal grade

or guaranteed figures. It may also be pointed out that the steadiness of the rate of "loss of charge" gives a valuable indication as to the soundness or otherwise of a cable under test, which is quite independent of the observed value at the end of the standard one-minute electrification. It is obvious that to measure the real dielectric resistance can give no advantage for cable-testing purposes over the conventional method, and the enormous difference in time required would necessitate the ratio of works area to test room area being inverted. Porcelain has been referred to in the paper and the appendix as an absorbent material, but it is not necessarily so. Porcelain can readily be obtained which is so thoroughly vitrified throughout its mass that it is non-absorbent and does not depend on its glazing for non-absorbency.

Finally, I can hardly agree with the statement contained in the author's conclusions, that it is customary to account for breakdown by dielectric stress. As a matter of fact the primary cause of a breakdown is hardly ever dielectric stress *per se*. In the vast majority of cases, whatever the primary cause, the presence of moisture is almost invariably found to be the chief contributory cause, and as the author's work appears to confirm very conclusively my opinions in this direction, the logical conclusion to my mind is that absorbent materials should be used as little as possible for general insulating purposes unless they can be either absolutely protected—as in the case of the paper-insulated cable—from access of moisture, or free to dry out under working conditions. There are other electrical points of view from which this is highly desirable, but they do not come within the scope of this paper.

MR. C. H. WORDINGHAM: The author has referred to "blind" tests, by which he means applying a high pressure and not knowing what goes on. I quite agree that such tests are very unsatisfactory and very unscientific; but I must say that, in my experience, I have found them exceedingly useful, and I am content to wait, as I have been waiting for a great many years, for Mr. Evershed to provide means to enable us to know what is going on. I should like to ask Mr. Evershed what is the date of Mr. Holt's experiments in Australia with the switches with porcelain bases. I know that about 1892 or 1893 Dr. John Hopkinson, with Professor Ernest Wilson's help, rather carefully looked into the effect of electric endosmosis, and I know that for some months after I had a good deal of experience with electric endosmosis on underground mains, largely on rubber cables in pipes. Reference has been made to porcelain being porous. Vitrified porcelain can certainly be obtained, and so far as I knew up to the present it was not porous; I have hitherto attributed all moisture effects to moisture on the surface of the insulator. The author does not seem to make any distinction in his paper, and probably quite rightly, between the conduction of the moisture within the material and the conduction of the moisture on the surface; but I think a great deal of the moisture must undoubtedly be on the surface. At all events, if long surface leakage paths are provided we all know that very much better results are obtained than with short paths, even though the distance measured through the dielectric may not be longer, or substantially longer, in one case than in the other.

MR. B. WELBOURN: As I read this paper I could not help thinking of a well-known quotation from Browning, Mr. Welbourn.

"Oh but a man's aim should exceed his grasp." I thought of this particularly at the end when Mr. Evershed suggested that the problem of forestalling breakdowns by systematic testing is nearly insoluble. Perhaps it is so, but with our present knowledge a great deal of systematic mains testing is being done, and a large proportion of insipient faults are removed from mains networks by regular testing without the consumer knowing anything at all about it. An extremely useful tool which has been provided for all mains engineers is the "Megger," for which I think Mr. Evershed is responsible, and which is an enormous advance on the old ohmmeter and generator. This in itself is a very good illustration of the rapid advance of knowledge. The author mentions, in a footnote on page 51, the flash test. I do not know whether the flash test is a "method of barbarism," but in my opinion it will not disappear very rapidly. I should like Mr. Evershed to suggest an alternative because all electrical circuits are liable to sudden pressure rises, and I do not know of any test which is in any way comparable with the flash test for showing up the suitability of the insulation to withstand these rises. I should also like to ask Mr. Evershed whether all the curves have been taken at uniform atmospheric temperatures, and whether artificial means were adopted to ensure that the insulating material was always at the same temperature, or whether the increasing dielectric loss due to the rise of the potential was allowed to heat up the dielectric. To all cable-makers especially it has been an exceedingly interesting problem to theorize as to why the insulation resistance of a cable should fall when pressure is applied and when the dielectric heats. This paper has thrown considerable light on the problem, and the author has convinced me that the theory put forward originally by Mr. Campbell and communicated to this Institution some years ago by Mr. Rayner and acknowledged by Mr. Evershed in his paper, is correct and that the effects are mainly due to moisture and air. I should further like to ask Mr. Evershed whether the fall in dielectric resistance is *only* due to moisture and air. The paper and impregnating oil themselves have physical properties which possibly change when electrical pressure is applied, and it may be that that also has some influence on these curves; but as far as I can discover from the paper the author gives no indication of his views on that point.

Now, for reasons given by the author, all the tests described in the paper have been made with continuous current, and some of them illustrate the causes of effects well known to all those whose work lies in the distribution of electricity by continuous current, such as the "valve" effect and the collection of dust and moisture through endosmosis. It reminds me of a particular use of the low-tension triple-concentric cable originated some years ago by Sir Alexander Kennedy where he made the core of the triple-concentric cable the negative pole instead of the positive pole, as is the usual practice, and I think it was effective in getting rid of some of the low insulation troubles with the neutral conductor on distribution networks. In these days when alternating-current work is so much to the fore, it would be very useful if the author could spare the time to make some tests with alternating current, and publish the results. There is no doubt whatever that the faults on alternating-current networks are far

fewer—in fact almost non-existent—than on continuous-current networks. To mains engineers, the application of alternating-current pressure for some hours is a well-known method of temporarily getting rid of low insulation on continuous-current mains if alternating current is available. I think some engineers might draw the inference from this paper that if we could get rid of all the moisture and air in absorbent insulators we should approach a sort of electrical millennium; but I would ask the author if he has considered whether it is really advisable to get rid of all the moisture and air. Every attempt that cable-makers have made to get rid of moisture has only resulted in brittle paper and the destruction of that flexibility which is so essential in handling cables.

Under the general title of "Characteristics of Insulation Resistance" one can rather range outside the exact contents of the paper. I have been very much impressed in the last few weeks in re-reading Dr. Russell's paper read before this Institution in 1907.⁷ In that paper a characteristic of insulation comes out in which moisture in a cable appears to play very little part, namely, the different behaviour of a given thickness of insulation with conductors of varying radius. In connection with Fig. 8, Mr. Evershed calls attention to the test taken after electrification for one minute, and this has already been referred to. The result is understood by all cable men as only being qualitative, but it gives an approximate idea of the true state of the insulation. Longer tests could be made if required, but, as Mr. Beaver has just indicated, there are limitations of time and space in every works.

Professor A. SCHWARTZ: On page 55 the author mentions that the only non-absorbent insulators which were tested in the course of his work were gutta-percha and rubber. He states that "these are both non-absorbent in the sense that what little water they may be capable of absorbing is entirely unable to form leakage paths through the insulator." While this statement may be quite true as regards gutta-percha and vulcanized rubber, it is hardly correct for pure rubber. The classical experiments of Thomas Hancock, which extended over 30 years—from 1826 to 1856—in which he hermetically sealed 12 ounces of water in a rubber bag and watched its evaporation from year to year, shows conclusively that at ordinary atmospheric pressure water is capable of being absorbed by, and of passing through, pure rubber. Pure rubber will absorb about 25 per cent by weight on prolonged immersion in water and increases considerably in volume; there is no doubt also that in its passage through pure rubber water very much affects the insulation resistance. In 1907 I tested some pure rubber flexible cables of 2,000-megohm grade; a 10-yard length was tested in air with a pressure of 550 volts, and the insulation measured between the conductors was found to be 6,000 megohms. On immersing the cable in water the insulation fell almost at once to 80 megohms; in a week to 40,000 megohms; and in 8 days it broke down with a pressure of 400 volts. A piece of vulcanized flexible cable put through a similar test showed, as in the author's case, that no appreciable effect was obtained. The amount of water that is absorbed by pure rubber depends partly on the character of the rubber, that is, on the amount of resin or oil which it contains, and partly on the physical condition of the rubber. Freshly

⁷ *Journal I.E.E.*, vol. 40, p. 6, 1908.

ssor
artz.

manufactured pure rubber absorbs water readily, but if the rubber is allowed to rest it becomes hard and comparatively inextensible, and in that condition it is more resistant to the absorption of water. Mr. Lester Taylor told me some time ago that he had had a pure rubber flexible cable feeding a 100-volt lamp for several months without any trace of breakdown, although immersed in water all the time.

I should like to refer to this question of the physical condition of rubber a little more in detail, because some of the changes that may take place in it are so considerable, and take place within such a small range of temperature, that when Mr. Evershed comes, as I hope he will do, to investigate the lower part of his curve, I think it would be interesting if he could consider the effect of these changes. (The speaker then exhibited the behaviour of a strip of rubber under the action of heat.) It is evident that the molecular condition of rubber undergoes a very considerable change at a comparatively low temperature; in determining the linear coefficient of expansion of a "rested" strip I found that this change takes place between 33° and 35° C.; up to 33° C. the rubber is in a hard and inelastic state, and above 35° C. it is in a plastic state. The author has described the state of things that obtains in the inside of a porous insulator. I have been interested in this subject from rather a different point of view, namely, in connection with the problem of the rise of sap in trees; and as a good many of our porous insulators are vegetable in origin, and since many of our inorganic insulators have a capillary structure, I think perhaps it would not be without interest if we consider very briefly what results have been reached by the physicists and the botanists who have been experimenting in this somewhat different field. In the first place we do not find in plants a continuous system of water channels; we find the bulk of the channels are intersected with innumerable longitudinal and transverse partitions dividing them up into very small compartments. It is rather curious, considering that the function of these channels is to take water from the roots to the leaves, that we should find them intersected nearly all the way up by numerous transverse partitions. We find, however, in the cells numerous air bubbles present, just as in the author's experimental tubes, and these bubbles, alternating with drops of water form Jamin's chains. The botanists consider that 10 to 50 per cent of the channels are filled with air, but I think that Mr. Evershed's resistance measurement method will help them in estimating more closely than they have been able to do by the microscope the proportion of channels which are filled with air. Now it is evident that whatever movement takes place in these chains of air and water—whether it is by endosmosis or by any other agency—the bubbles will not be able to pass through the partitions, and where we have long cells a bubble forming in one of these will put a large proportion of the conducting tube out of action, or at any rate it will introduce a very high resistance in the conducting tube. But by dividing the conducting tube up into a number of small cells by means of transverse partitions we have the size of the bubbles limited, and we see that if a cell is put out of action, or has extra resistance introduced into it by means of an air bubble, the length of the high-resistance film is limited by the length of the

cell. The fact that the bubbles are confined in very small cells by longitudinal partitions means that only an infinitesimal portion of the whole of the conducting area of the circuit is interfered with by a bubble. An interesting reference was made by Professor Silvanus Thompson to the question as to whether we should ever be able to get material with pores small enough to prevent the ingress of water. I am afraid that the work of botanists shows us that the smaller the pores the more easily the water-vapour gets into them. Messrs. Brown & Escombe found in 1900 that the diffusion of water-vapour through a number of minute pores in an impermeable membrane will be greater than through one large aperture having a cross-section equal to the area of the pores. This is due to the increased efficiency of transmission at the periphery of the aperture as against the efficiency of the transmission at the central portion of the orifice, and as the size of an aperture is reduced the relation of its margin to its area is increased. The prevailing idea in botanical circles as to the rise of the sap is that it is due to tension in the water induced by evaporation. I do not know that the possibility of an electrical cause has been considered, and I should like to ask the author in this connection what is the lowest voltage at which he has found endosmosis take place.

Professor
Schwartz.

Mr. E. H. RAYNER (*communicated*): Those of us who have worked on insulation know that the labour apparent in any paper on insulation is only a small proportion of the amount which has actually been spent, a large proportion of the experimental work being the unmentioned preliminary experiments, which give the author the moral authority to publish the results of such final experiments as he deems of value. Before turning to the one point upon which I especially desire to dwell, I should like to suggest that notes on the effect of a few degrees' change of temperature would be instructive. Without experimental experience it is difficult to realize how greatly the resistance of an absorbent insulator may change with quite a small variation in temperature. The possibility of moisture being associated with mica is mentioned on page 60. When testing mica under a high voltage I have often noticed that the violence of the brush discharge on the surface diminishes after the first few minutes, which I have ascribed to driving off a surface film of moisture. Some further details as to the dimensions of the apparatus used in measuring the resistance of oil would be of use. Do the numbers in Fig. 21 refer to the actual resistances as measured, or to the value per cubic centimetre? The absorption curve for the oiled paper cable is very interesting. Does the author think the same resistance would be obtained if the paper were absent and the same quantity of water associated with oil only? And does the paper plus oil absorb much more moisture from the air than the oil alone would? Some note as to the "natural" amount of water in the paper used for the experiments in Table I would be of interest. There is no mention as to whether this condition falls within the limits of the experiments described. It is very satisfactory to find that the results of my own work mentioned on page 65 agree so well with those of the author.

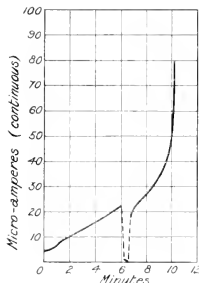

Mr. Rayner.

I now turn to one particular point which has been

* BROWN & ESCOMBE. "Static Diffusion of Gases and Liquids in Plants," *Philosophical Transactions of the Royal Society B*, vol. 193.

mentioned by Mr. Wordingham and other speakers. On page 51 the author asks, "What is the margin between working voltage and breakdown? That is the fundamental question at the root of every inquiry into the properties of insulation. To conduct tests without any means of ascertaining what is going on in the insulator as the breakdown voltage is approached, without either observing the current or, better still, the resistance, is to shut our eyes and deliberately avoid looking for the cause of failure." And again (on page 71) he asks "whether it is possible to predict the breakdown voltage. . . a blackened hole appears in the insulation and the inference is too hastily drawn that the puncture process was instantaneous. . . The time may never come when it is possible, by systematic insulation testing, to forestall breakdown by diagnosis of the disease and removal of the cause." Within certain, possibly wide, limits I think

weak places in the insulation, more especially where the conductivity is greatly increased by any local heating at dangerous spots. In testing small pieces of insulating cloth ample warning is given of the approach of breakdown. Whether the method can be as usefully employed for finished machines can only be determined by trial. The apparatus consists merely of a sensitive moving-coil ammeter (a micro-ammeter by R. W. Paul) and a battery inserted at any convenient part of the circuit. Small cells for pocket lamps can be mounted compactly, so that a battery giving a pressure of 100 volts weighs about 12 lb. Fig. A shows a diagram of the connections and the result of a test on three thicknesses of Empire cloth wound on a cardboard tube with tinfoil electrodes, the area being 130 sq. cm. The alternating voltage was 2,500 and the continuous voltage 100. The continuous voltage alone produced no perceptible current in the instrument. On

FIG. B.

the answer is already in the affirmative. It is possible, with simple apparatus, to test insulation of an organic and absorbent nature under an alternating voltage, and to see exactly what is happening; to learn whether the insulation is likely to withstand the voltage indefinitely, whether and how soon it is sure to fail, with the great advantage that the pressure test may be stopped before permanent damage is done. Some method of determining whether an electrical plant is insufficiently dried out for running for the first time after erection could not but be of great commercial value.

As the author states, alternating-current measurements are useless in showing the leakage current through insulation, as it is exceedingly small compared with the capacity current. An alternating-current wattmeter will give the required information; but it is hardly a practicable workshop instrument. It is, however, practicable, while applying a high-voltage alternating test pressure to insulating material, to add in the circuit a much lower continuous potential which will find its way through the

switching on the alternating current the ammeter indicated 4 micro-amperes, which increased in 6 minutes to 21 micro-amperes. On switching off the alternating voltage the reading falls to 1 and diminishes still further. On switching on again, the alternating voltage causes instantly a great increase in the continuous current, and failure rapidly takes place.* The very great drop in the continuous current on switching off the alternating voltage is important. It shows the futility of assuming that the insulation resistance of a high-voltage machine under working conditions can be assumed from tests made by much lower continuous potentials. Fig. B shows the result of a similar test at a lower voltage (2,000), which was applied for 40 minutes and then raised to 2,250. As in the previous experiment, the alternating voltage was switched off for half a minute and the experiment was stopped a minute after switching on again a few seconds before actual failure occurred. The material has become

* E. H. RAYNER, "High-voltage Tests and Energy Losses in Insulating Materials," *Journal I.E.E.*, vol. 49, p. 47, 1912.

layer, darker locally over an area of a few square centimetres, but actual puncture has not taken place. I do not know that the method has been tried on finished machines. It will be seen that the alternating current traverses the continuous-current instrument and causes some vibration of the pointer unless this is very stiff. The only difficulty would appear to be the alternating capacity current, which would be much larger than when testing a comparatively small piece of insulating material. No doubt a specially rigid moving system would be of considerable help and might suffice. The instrument might have a very large inductance added to it, say the primary of a switchboard potential-transformer, and the ammeter and inductance be shunted by a large condenser through which most of the alternating current passes. Mr. Irwin tells me that he has found an inductance of 4 henries and a capacity of 20 microfarads successful. The condensers should be protected by a spark-gap, as the full voltage would come on them if failure occurred in the insulation under test.

Mr. C. P. SPARKS (*communicated*): Mr. Evershed raises an interesting question: "What is the margin between working voltage and breakdown?" and suggests that the problem should be determined by continuous-current insulation tests rather than by the application of an alternating-current pressure test; the difficulty of using any sensitive instrument with alternating current is pointed out in Section 2 of the paper. While I am in agreement as to the advantage of using an indicating instrument, this has yet to be evolved for alternating current, and until this is possible I am in favour of continuing the use of alternating-current testing, not in the form of a flash test referred to in his note, but in the form of an alternating-pressure test applied for short periods. At present this is the only feasible method of testing high-pressure apparatus, and is a more reliable indication of the condition of the plant than can be obtained by a continuous-current insulation test carried out with a pressure of a few hundred volts. Section 4 of the paper refers to the relative importance in wiring between the leakage through the dielectric used to insulate cables, and the leakage through fittings. The importance of the leakage from fittings was appreciated by the Institution Wiring Rules Committee when amending the rules some years since, as is shown by the following extract from Rule 121:

"121. The insulation resistance to earth of the whole or any part of the wiring must, when tested previously to the erection of fittings and electroliers, be measured with a pressure not less than twice the intended working pressure, and must not be less in megohms than 30 divided by the number of points (par. 32) under test. For this purpose the points are to be counted as the number of pairs of terminal wires from which it is proposed to take the current, either directly, or by flexibles, to lamps or other appliances."

Section 13 of the paper deals with a model insulator tested with continuous current. Have similar tests been made with alternating current? These should show the breaking up of the films between the separate drops of moisture, thus increasing the insulation resistance. In conclusion, Mr. Evershed's paper will be welcomed by all, as it demonstrates the initial reason why alternating-current cables and other apparatus are far less troublesome to maintain than continuous-current apparatus when worked under equal dielectric stress.

Mr. A. T. BARTLETT (*communicated*): I welcome the Mr. Bartlett research described in the paper as one of great value, not only for the actual results already obtained but for what it may, and I hope will, lead to. Such methods and knowledge should help us to select our insulation materials in a more rational manner and, it may be, to produce new and more satisfactory forms of flexible insulators; but from the dynamo and motor manufacturers' point of view I must in common with two other speakers protest most emphatically against the author's condemnation of the flash test. I believe that few engineers understand the real object the plant manufacturer has in view when he fixes and applies a definite flash or pressure test. It is not applied, as many seem to imagine, simply to find out whether the insulation will stand a definite pressure between, say, the windings and the shell—having provided a factor of safety, he knows it will, unless the material has been damaged or has faulty spots which could not be detected before use. If any such weak points occur he wants to discover them, and I know of no other method which can approach the pressure test for this purpose, because it is not only necessary to know that such weak points exist, but they must be located, and even in "a costly piece of electrical apparatus" it is cheaper in both time and cost to burn the fault out; at this stage he is not concerned with what actually happens to the damaged insulation at the moment of breakdown. To emphasize the real object of the flash test, I may say that it has been my practice to fix the voltage of the flash test quite independently of the working voltage, e.g. in the case of a low-voltage, say 50 volts, generator, if I know that the insulation materials in that machine are identical with a machine built for a working voltage of 500 volts, as is frequently the case, I test for damage to the insulation with a 2,000-volt pressure test, which may appear to be heroic, but is good sound practice; I should imagine that cable-makers have probably the same object in view. Anyone who has had experience on the test-beds knows that an insulation test even when applied at a more or less high pressure by means of a 1,000-volt testing set often fails to reveal the presence of air-filled cracks in the insulation, simply because there is not sufficient power behind the test. Hundreds of cases have occurred in which machines have broken down under a pressure test after having just previously shown high-insulation results with high-voltage testing sets. The plant manufacturer can no more forgo his pressure test than can the crane- and lift-builder or boiler-maker forgo his overload stressing tests.

To the plant builder the experiments on the varnish-impregnated cotton-covered wire are of great interest, and my own experience agrees with the results obtained, viz. that the effect of such impregnation is quite ephemeral. I have for years unsuccessfully advocated that all field coils of such machines as are to work in an ordinary weather-proof building should be wound dry and varnished only on the outside layer, or taped over and varnished. Impregnating such coils has practically no effect on the dielectric strength to earth, and reasonably dry cotton is ample insulation between the turns and layers in a well-designed coil. I have seen a number of the old field coils of ancient two-pole machines unwound in which the cotton was in excellent condition, although wound dry. On the other

hand I have seen a number of cases of impregnated coils giving trouble owing to the varnish breaking down and acquiring an acid reaction; this is a real danger and one which in my opinion it is quite unnecessary to run. The author mentions stoving his varnished materials at 150° C., which I do not think can be recommended; he referred to a special varnish which he uses, and if he has a varnish that will stand this temperature not only on a thin coil such as he used, but in a normal field coil—in which the solvent in the interior takes many years to evaporate or oxidize—then I hope he will disclose it as it might be of great value in such cases where impregnation is advisable.

Mr. A. CAMPBELL (*communicated*): As one who attaches great importance to consistent nomenclature, I regret to see that the author uses the term "characteristic curve" quite out of its ordinary meaning (*i.e.* volt-ampere curve). To give any scientific term a double meaning reduces its efficiency by much more than 50 per cent. The author's theory appears to be well supported by many experimental results, and in particular by the behaviour of his beautiful model, but I fear that the examination of a wider variety of absorptive insulating materials will make the theory more difficult to accept. Some years ago in experimenting on fibrous insulating materials (like paper) at various temperatures I came to the conclusion that the effects observed had their origin in the tubular structure of the fibres. Not long afterwards I found that solid cellulose behaved very much like ordinary paper. Now the solid cellulose is a fibreless colloidal material (like a sheet of glue), and its pores must be of a quite different order of magnitude from those of paper. Since reading Mr. Evershed's theory I have had a few rather hurried experiments made on some colloidal materials, which have given the following values for the "Resistance Ratio" for V_2/V_1 —

Solid cellulose	2.7
Celluloid	1.2
Cellulose acetate...	1.0

The third material is the well-known flexible enamel now so much used for covering wires; it is somewhat absorbent of moisture, but not nearly so much so as any form of cellulose. It will be noticed that the other two colloids show "Resistance Ratios" greater than unity, and yet their glossy structure does not suggest porosity in the ordinary sense. It appears to me, therefore, that the effect of moisture is mainly molecular, not explainable by the assumption of water films working in microscopic channels. Cellulose and other similar colloids appear always to have (at any given temperature and pressure) a certain proportion of water associated with them, part of which may be in loose chemical combination, and the remainder, as it were, in solution in the colloid. The tubular structure of some of the fibrous forms of cellulose no doubt must have considerable influence on their behaviour as insulators, but any theory must take account of the ultimate colloidal nature of the material. I hope the author will examine the behaviour of some of the non-fibrous absorbent insulating materials (Bakelite for example) and if necessary widen his theory to include them all.

Mr. G. E. BARSTO (*communicated*): I should like to ask the author whether in the analysis of his results he has fully taken into account the nature of the contact used in

his experiments. He uses copper plates interleaved with the sheets of dielectric. Now it has been shown by Mr. Appleyard,² and recently in more detail by myself,¹ that in using tinfoil, which is obviously even better suited than copper plates for producing a more intimate contact with the dielectric, an increase of voltage has a very considerable influence in producing an apparent decrease in the resistance as the voltage is increased. This will take place even with a very high compression of the dielectric, say 15 or 20 lb. per sq. in. The more rigid copper plates used in the present experiments would tend to enhance this effect. There are two points described in the paper which make me suspect that the imperfect contact is responsible to a certain extent for the rapidly falling characteristic curve shown in most of the figures. The first is in Fig. 5, in which we have a so-called hysteresis effect depending upon whether the voltage is increasing or decreasing. Now this hysteresis effect is well known to those who have studied tinfoil contact with ordinary dry dielectrics, and is due to the influence of the voltage in pulling down the electrodes into contact with the dielectric. The second point is illustrated by Fig. 17, where the change of characteristic from a gradually falling curve to a straight line, as the dielectric becomes sodden with water, is explained as a change from "moisture conduction" to conduction by Ohm's law. It could, however, be explained in quite a different manner. Starting with a dielectric having a resistance independent of the voltage, curve A may be taken to represent the influence of voltage in bringing about a more intimate contact as has just been described. In curve C, however, the paper being now sodden with water will have a surface film of moisture, allowing the current to creep along the face of the dielectric from the points at which the electrode is in contact, to, and through the parts of the dielectric which are not touching the electrodes. That is to say, the effect of the presence of the moisture film is to produce a contact which is almost as good as if every part of the dielectric were in thorough contact with the electrodes. We should then get, as in curve C, a straight line showing a resistance independent of the voltage. I do not maintain that all the effects described in the paper are due to this effect, but I feel sure that it has had a considerable influence. It cannot be separated out, and the only way in which comparative tests can be made is by employing mercury electrodes. I may mention that in a long series of experiments made at University College it has been found that at low-potential gradients up to about 5000 volts per cm. there is no variation of resistance with voltage, and this is true for such widely different dielectrics as mica and celluloid, using ordinary dry materials and mercury electrodes. As the potential gradient is still further increased the resistance falls away in a manner similar to that depicted in the lower portion of Fig. 1. Supposing, however, that the results obtained by the author represent the state of affairs for damp insulation, then it must be agreed that what we are discussing is not the characteristics of insulation at all, but rather the characteristics of water in insulation.

Mr. R. D. GIFFORD (*communicated*): It is apparent that this paper is the outcome of a very thorough investigation. It is probably only those who have had to make resistance

¹ *Proceedings of the Physical Society of London*, vol. 10, p. 724, 1905.

² *Ibid.*, vol. 25, p. 301, 1913.

and breakdown tests on insulators who can really appreciate how fully the factors which usually go to obscure the truth have been recognized and taken account of. There is one point, however, to which I should like to call the author's attention, as I do not see it mentioned in the paper. He says, on page 53, that the source of current was usually a 500-volt battery, and occasionally a small 1,000-volt generator. The author has emphasized in several places in the paper how greatly the true value of the insulation may be masked by the capacity current, which effect must be considerable where we are testing the insulation resistance of a cable or network of feeders. Now the E.M.F. of a battery may be represented by a smooth line, but surely the E.M.F. of a generator cannot be so represented; it must have a surface ripple, since it is made up of a number of commutated waves. Under these circumstances it is apparent that a capacity current will be superposed on the insulation current, vitiating the results to a greater or lesser degree. Moreover, the ripple will be much more conspicuous in the case of the small generator E.M.F. than in an ordinary continuous-current supply, as the number of commutator segments is necessarily relatively few. I shall therefore be glad if the author will state whether he made any tests, such as with an oscillograph, to ascertain the magnitude of these ripples, and also if the results obtained when using the generator were consistent with those obtained when using the battery.

Mr. P. J. COTTE (*communicated*): Mr. Evershed's paper is of great interest to telephone engineers who are confronted with the problem of maintaining the insulation of dry-core cables. The pictorial representation of the action of moisture in reducing the insulation resistance of absorbent insulators may throw some light on many desiccation problems. In this country it is usual to desiccate paper-core cables with dry air, but French telephone engineers have recently extensively employed dry CO₂ for this purpose. Apart from considerations of cost and inconvenience it is claimed that a certain volume of dry CO₂ is more efficient than an equal volume of dry air for raising the insulation of a paper-core cable. It is found on the completion of desiccation with CO₂ that the insulation has been raised by an amount quite equal to that obtained by using an equal volume of dry air, but that in the former case the insulation resistance continues steadily to rise after the completion of desiccation. Does the author consider that owing to the greater density, and the consequent slower rate of diffusion of CO₂, this gas should be more effective than air in reducing the proportion of water in the paper which acts as a conductor?

Dr. A. W. ASHTON (*communicated*): In adopting the conclusions arrived at by the author we must not lose sight of the fact that the testing pressure was continuous and that the materials tested gave results mainly determined by the amount of moisture absorbed. In cases where the leakage is neither due to absorbed moisture nor surface moisture the true dielectric leakage is proportional to the applied voltage. In the paper this is shown to be true in the case of cylinder oil (see Fig. 21, Curve A) and varnished cotton (see Fig. 24, Curve A). This true dielectric leakage, determined by prolonged charging at a steady pressure, is only of use as an indication of the presence of conducting impurities in the dielectric. On the other hand the apparent conductivity after one minute's electrification

is, I believe, much more important in the case of a good dielectric than it is generally considered to be. According to what may be called the Pellat-Schweidler-Hopkinson theory of dielectric absorption, there is a direct relation between the charging current after one minute's electrification and the energy loss under an alternating E.M.F. If this theory is true the so-called insulation resistance in the case of a cable free from faults gives an indication of its capability of withstanding the prolonged application of an alternating voltage, where breakdown is probably due to an increase in temperature caused by dielectric losses.

With regard to "blind" tests of breakdown voltage, there are two factors for the determination of which the breakdown test is of use, viz. the effect of the geometrical form of the insulator and the strength of the dielectric to resist disruptive discharge. The application of the flash test will detect the presence of faults due to design or to manufacture, and will determine whether the dielectric is able to withstand the unavoidable transient pressure rises due to switching on, etc. On the other hand the prolonged pressure test during which the material is kept under observation by measuring the energy dissipated, will enable the possibility of changes in the dielectric due to electric stress or to temperature rise to be investigated.

Mr. S. EVERSHED (*in reply*): The discussion has extended a good deal beyond the area covered by the paper, and the many interesting matters touched upon by the several speakers serve to remind us of the enormous area as yet unexplored in the field of insulation. In replying to the discussion I must, however, confine myself to those points which bear directly upon the facts recorded in the paper.

Dr. Thompson spoke of the extraordinary difficulty there is in keeping water out of an absorbent body. At present, as he said, it seems quite impossible to keep it out, and until the great discovery, which he referred to, is made we must put up with what Nature has given us. I should like to point out that but for the marvellous power an absorbent body has of stowing away almost the whole of the absorbed water in an electrically dormant state much of the work we now do would be commercially impossible. If the whole of the absorbed water took part in making leakage paths, low-tension networks as we know them would be useless. In such networks we do not measure insulation by megohms, but by amperes sometimes a great many amperes; for the leakage current depends on all sorts of circumstances—and on the mains engineer. But if Nature had allowed all the absorbed water to conduct, then for every ampere leaking under present conditions we should have had a leakage current of many thousands of amperes. Nature is sometimes on our side. I was very much interested in what Dr. Thompson said about the inevitable instability, the complex motions, of water which is carrying an electric current. When we look through the microscope at the films in our little glass model the unstable motions are going on under our eyes. We see why individual tubes are often so extraordinarily unstable. At one moment the film water will be travelling along in one channel, and the next moment, for no apparent cause, it will divert itself into another path altogether. But this of course refers to water films on glass, and I suspect that the extremely smooth surface of the glass accentuates the

instability. It may well be that in that respect glass is not truly representative of other insulators. Dr. Thompson asked whether the moisture curves obtained by first ascending and then descending the voltage range formed loops or not. They certainly make a loop, and there is an accompanying waste of energy. When the potential difference is applied the hydraulic force of endosmose is utilized (1) in overcoming the quasi-elastic capillary force of the film into which the dormant water is driven, and (2) in overcoming the fluid friction of the moving water. Upon switching off the pressure, the surface tension of capillary force of the film very slowly forces the surplus water out of the film into the adjacent water drops, and in so doing the reversible energy stored in the form of surface tension is all frittered away in overcoming the fluid friction incurred in driving the surplus water back into the dormant drops. Hence in going through a complete voltage cycle the whole of the energy due to the endosmose action is lost—degraded into heat. And since the surplus water retires into the drops with extreme slowness, and the flooding of the film may be made to take place almost instantaneously if we choose to apply a high potential difference, the area of the loop and waste of energy may evidently be reduced to any extent by performing the cycle with great rapidity. The analogy with magnetic hysteresis is evident. There is the "lagging behind" and the waste of energy, and if only we had the power to perform a complete magnetic cycle so quickly that Ewing's little magnets had barely time to move, the magnetic loop could doubtless be reduced in area to the same extent as the loop in a rapidly executed cyclic moisture curve. But the analogy must not be pushed too far.

Ohm's law is a perennial stumbling-block. I was taught to believe that it is comprised in the statement that "a current through a given conductor is proportional to the E.M.F. which drives it."* When we find a conductor in which this proportionality does not hold good (notwithstanding the fact that the conductor undergoes no apparent change in its dimensions or in its temperature), then we are justified in saying off-hand that it does not follow Ohm's law. But we do not for a moment believe that Ohm's law has failed us. On the contrary we suspect at once that our "given conductor" has in some occult way altered its electrical dimensions and changed its resistance. When we examine the case of the absorbent insulator we discover that the absorbent body which we assumed to be the "given conductor" is not a conductor at all. We find that the actual conductor is made up of a number of films of water and that each film has its sectional area increased as the potential difference increases. And in this way the apparent failure of a law which we believe to be universally true is accounted for. I have never heard the universal truth of Ohm's law more clearly expressed than it was by Dr. Thompson, and although he and I do not speak the same language I agree with every word of his statement. But I shall continue to speak the language I have been accustomed to all my life, the free and easy speech of everyday intercourse. I shall continue to say the sun rises, although I know perfectly well that he only appears to rise because I happen to live on a revolving planet.

I quite agree with Mr. Beaver that it is commercially impracticable to measure the insulation resistance of rubber-covered cables, since each test might occupy 24 hours. I do not object to the cable-maker measuring the charging current plus leakage current at the end of one minute if the test gives him useful knowledge, but I confess I should like to see the phrase "insulation resistance" restricted to its proper use, undiluted by charging current.

Mr. Wordingham expressed the hope that means would some day be forthcoming by which it would be possible to see what was going on while the insulation is undergoing a pressure test. The means have been available for many years past, but we have not chosen to take advantage of them. All that is necessary is a high-tension continuous-current dynamo, and a galvanometer to give timely warning of latent defects. So far from being averse to high-pressure tests, as a manufacturer I regard them as absolutely indispensable. But I want to see an improvement in the usual mode of conducting them; let us have our eyes wide open. Mr. Wordingham also drew attention to the effects due to moisture on the external surfaces of insulators. In the early stages of our research we made several attempts to investigate the law of conduction in films on external surfaces, but experimental difficulties have so far prevented us from arriving at any useful results. External films are unlikely to give a moisture curve because in the absence of drops on the surface there is no dormant water available to flood the film. No doubt the action of endosmose, if sufficiently prolonged should result in an increase in the resistance of the film, provided the water is driven away from the positive electrode at a greater rate than that at which fresh water is being deposited out of the air.

I was very glad to hear what Mr. Welbourn said about the systematic testing of distribution networks. It is indeed good to know that already a large proportion of latent defects are discovered and removed; to know that in a great many cases breakdown is forestalled. But when I refer at the close of my paper to the problem as a whole seeming almost insoluble I am thinking of the complete system, from the plant in the power house to the installation on the consumer's premises. The mains may be cut up for the purpose of testing, but it is impossible to cut up the generator and transformers, and it is in such things that the difficulties of diagnosis are greatest. It is there that our aim exceeds our grasp. Mr. Welbourn referred to a number of interesting phenomena which are familiar to the cable-maker and the mains engineer, such as the marked difference between the number of faults occurring on continuous-current and alternating-current networks, and the use of alternating current as a remedy for low insulation. These things are but vaguely known to those who, like myself, are interested in tracing the causes of such effects, and I feel sure there is room for a good descriptive paper on the subject written by someone who has first-hand knowledge.

Professor Schwartz drew our attention to the difference between pure rubber and vulcanized rubber as regards absorption of moisture. Hancock's experiment has never appeared to me as conclusive because I have never come across any rubber that did not perish after two or three years' exposure to the air, or to water containing air in

* OLIVER J. LODGE. "Modern Views of Electricity," p. 69, edition 1886.

solution. After such exposure the rubber is full of minute cracks. The poor insulation results obtained with flexible cables insulated with pure rubber are, I think, as much due to imperfect joining of the rubber strip round the conductor as to porosity of the rubber. What Professor Schwartz told us about the structure of the capillary passages up which the sap finds its way in a tree-trunk (and I suppose in any plant) cleared away some of the obscurities as to the disposition of the dormant water. There are evidently plenty of cells—blind alleys—to harbour it. But where are we to place the conducting films, with all those cross-partitions apparently blocking the way at intervals along the passages? I think the answer is that since the sap goes through the partition they must be porous; and in the pores are the films, with bodies of dormant water lying close at hand on both sides of the thin wall. A disposition of that kind is particularly well adapted to produce the endosmose effect, as Mr. Finnis and I have already discovered by experiments on thin porous tubes. I can only answer the question Professor Schwartz put to me about the limit potential gradient below which endosmose will not take place by saying that I do not think there is any limit. The lowest gradient at which I have actually seen the water pouring out from a drop into the film was about 25 volts per cm.; but judging by the decrease of resistance, the effect begins a long way below that point.

While I have been investigating the first part of the characteristic curve, Mr. Rayner has been at work at the National Physical Laboratory on the last part of the breakdown curve. His method of testing by superposing alternating current on continuous current is very interesting, and the resulting effects are quite new to me. He was kind enough to communicate the preliminary results to me a few days ago, and I asked Mr. Finnis to carry out similar tests on a piece of vulcanized rubber flexible. With defective cable we get just the same kind of effects as those which Mr. Rayner has described to us. What the explanation may be is another matter. And this reminds me that several speakers have referred to the effect of temperature on the characteristic curves. When the insulator is near the breakdown point it may easily be that a large amount of power is being spent in heating it. This has already formed the subject of an interesting paper which Mr. Rayner gave us last year.² But throughout the moisture curve the power spent is almost immeasurably small, and hence there is no sensible heating of the insulator. We have never observed any appreciable rise of temperature in making tests on the first part of the characteristic curve. Replying to Mr. Rayner's question, the resistance values in Fig. 21 are those actually measured; the test was purely qualitative.

Mr. Campbell tells us that since reading the paper he

² *Journal I.E.E.*, vol. 49, p. 3, 1912.

has carried out "a few rather hurried tests" on colloidal materials, and he gives us the resistance ratios obtained. These are, however, no criterion for a voltage-resistance curve, in the absence of any knowledge of the shape or law of the curve. I hope Mr. Campbell will continue his investigation of colloidal insulators and give us curves based upon a prolonged experience of their behaviour.

Mr. Bairsto refers to the effects occurring at the contact between electrode and insulator. In the earlier stages of our research Mr. Finnis and I attempted to find an explanation of the moisture curve at the terminals, but like many other hypotheses which occurred to us, it entirely failed to provide an explanation in agreement with all the facts. It was not until we directed our attention to the inside of the absorbent insulator that we made any progress at all.

Mr. Gifford mentions the small capacity current due to the ripple superposed on the E.M.F. of a testing generator. This is of course an alternating current and does not affect the reading of the galvanometer, or ohmmeter, one way or the other.

Mr. Sparks refers to the Institution Wiring Rule No. 121 as it now stands. This rule is based on the number of pairs of terminals from which it is proposed to take current. This is very far from being the same thing as the number of leakage points, and, as I have pointed out in the footnote on page 57, it is the average resistance per leakage point which enables us to judge whether an installation is in good or bad order. Incidentally I may suggest that the ordinary wireman would more easily multiply the ohmmeter reading by the number of leakage points than perform the simplest division sum. I share his weakness. Mr. Sparks suggests that the application of an alternating potential difference should break up the films in the model insulator. I have not tested the model with alternating current, but I have little doubt that Mr. Sparks is right. I think the film water would tend to collect in a heap halfway between the surfaces of the adjacent drops; but *that* experiment.

Fiat experimentum. Perhaps that is the best answer to those friendly critics of my paper who have expressed a healthy scepticism with regard to my theory of moisture conduction. Let them test a few typical absorbent insulators. Let them make up a bundle of capillary tubes and test them. Put a tube under a microscope and watch the behaviour of the drops and films. They may then feel more confidence in taking the step which I have taken: the step from what I have seen in the tube to what I infer in the absorbent insulator. On the other hand they may unearth fresh facts which give my theory its quietus. Time will show.

In conclusion, I can only say that Mr. Finnis and I shall go forward with the investigation of the breakdown curve, greatly encouraged by the cordial reception which has been given to this paper.

DISCUSSION ON

"THE BRITISH STANDARD SPECIFICATION FOR CONSUMERS' ELECTRIC SUPPLY METERS." *

BIRMINGHAM LOCAL SECTION, 12TH NOVEMBER, 1913.

Mr. S. W. MELSOM: It is most desirable that any alteration of the existing specification should be very fully considered, and in putting forward a number of suggested new clauses as a basis of discussion Mr. Holden is doing a very real service. I do not, however, altogether agree with some of his suggestions. To take the clauses in detail:—

Clause 2.—I quite agree that it is desirable that the range of meters covered by the specification should be increased, but in view of the importance of large meters I hope that any revision will not limit the size to 500 amperes, but will include all "consumers' electric supply meters."

Clause 3.—While cast-iron or pressed-steel cases are apparently quite satisfactory for small meters, I do not think they would do for large ones. With a short-circuit current such a case would be liable to become permanently magnetized and to cause large errors in the subsequent meter readings.

Clause 6.—Mr. Holden's proposal to connect cables for currents up to 500 amperes by means of two screws clamping the cable into a hole, is somewhat revolutionary. Apart from the fact that the size of the holes he suggests would not be quite large enough to take some cables based on the Institution Wiring Rules (taking a 91/12 cable, Institution rating 490 amperes, for 500 amperes the diameter of the strand is 1.012 in. as against 1 in. allowed by Mr. Holden), the suitability of such a type of connection for large cables should, I think, be very carefully considered. Present-day practice, not only in connection with switches, fuses, and other gear, but of meter manufacturers, provides for sweating sockets for such cables; in fact, the Institution Wiring Rules provide that all cables larger than 7/18 S.W.G. must be soldered to proper lugs for connection. Meter makers almost without exception provide for 500-ampere meters either soldering sockets or flat surfaces to which copper strip can be bolted. It would be useful to have the opinion of the manufacturers as to whether it is desirable to scrap all the existing patterns for one which is probably inferior to any of those now in use. Apart from this, however, the question of connections is of the greatest importance, and I venture to suggest that the meter specification should be considered in this respect by the Wiring Rules Committee, and also with reference to any existing specification, such as that for ammeters and voltmeters, so that substantially the same type of connections might be allowed for all classes of apparatus used in a permanent installation. The manner in which cables are run to large meters is also very important, and I hope that any revised specification will deal with this point.

Clause 10.—It does not seem to be altogether desirable to rule out such meters as the electrolytic and the commutator ampere-hour meter, which require a pressure drop

of about 2 volts, and I therefore think that the 2-volt drop should stand for small meters. With regard to the voltage drop suggested for large meters, Mr. Holden's figures are no doubt based on shunted meters. So far as present practice is concerned I think that the limit of 0.075 volt suggested is too low and that for large shunted meters it should be of the order of 0.2 volt. The loss of power even for a large meter would not be excessive, and I think that most people would prefer to lose rather more power if by so doing they could obtain a more accurate meter. For unshunted meters, however, this limit is too high, since such an amount of power dissipated in the meter itself would give rise to large errors due to heating, and I would suggest therefore that there might be some differentiation between shunted and unshunted meters, specifying a maximum voltage drop for the former and a limiting number of watts for the latter.

Clause 17.—While for alternating-current meters the limits suggested by Mr. Holden may be satisfactory, I would point out that for a 480-volt continuous-current meter the limit of 7 watts which he suggests (about 1.5 watts per 100 volts) is much lower than that required for the great majority of meters, and I shall be interested to learn whether in his opinion a motor-type meter can be made to work satisfactorily with such a small loss in the pressure circuit.

Clause 20. *Accuracy*.—I note that Mr. Holden suggests the same limit of error for both large and small meters, and I should like to have his opinion as to whether, when taking into consideration all the factors involved, a small meter can be expected to conform to the same limits of error as a large one. I do not suggest that the limits for, say, a 10-ampere meter should be increased, and perhaps I might put it in another way, namely, whether it is not desirable that a 500-ampere meter, where a year's record would probably represent several hundred pounds sterling, should work to a somewhat higher degree of accuracy than a small ampere-hour meter in which the year's record would probably be represented by only a few pounds. I admit that it is a purely commercial question with which perhaps I am not competent to deal, but probably we shall have some expression of opinion from those who are more conversant with the commercial side of the question.

Clause 26. *Wave-form*.—Mr. Holden's suggestion of a limit of error for a change in wave-form would, I think, be very difficult to apply. In testing, it would involve the production of a wave-form with all the possible harmonics, and it seems probable that such a clause could not really be applied in practice. Generally speaking, one would expect that a meter which is unaffected by large changes in frequency would not be affected by slightly varying wave-form.

* Paper by Mr. S. H. Holden (see p. 39, No. 223).

Melton. *Overload.*—With regard to overload capacity, Mr. Holden thinks that such a clause should be deleted, but at the same time I would point out that practically all meters will stand large overloads for short periods, and, moreover, the deletion of such a clause would tend to the undesirable practice of installing meters which are far too large for the average load. Particularly is this the case in traction meters, where the current may rise for a few seconds to about five times the normal full load. The question of overload for meters used on a traction circuit will, I hope, receive careful consideration in any new specification. I regret that time has not permitted of my dealing fully with Clauses 25, 26, and 27, but I hope that these clauses will be discussed by other speakers.

Mr. R. A. CHATTOCK: I think it is quite time that this specification should be revised and brought up to date, and the suggestions made by Mr. Holden should be very valuable for this purpose. I do not agree that frequent revision of the specification is necessary, and I consider that once every five years is quite sufficient; oftener than this would render the specification practically useless for commercial purposes. The author emphasizes the point that the specification should be sufficiently rigorous to exclude all but the best articles, but he does not indicate how this should be done. This is the most important consideration from the purchaser's point of view, and I suggest that the only feasible way of ensuring that the best materials and workmanship are used is to require a long period of guarantee, covering the accuracy, material, and workmanship of the meter. The specification requires only one year's guarantee for accuracy, and three years for defective material and workmanship. I understand that it is usual to guarantee gas meters for a period of five years under all these headings, and I consider that five years should be the period required in connection with electricity meters; if this were insisted upon, it would ensure that the manufacturers put the best materials and workmanship into their goods. Defects in meters very often show up two or three years after the meters have been installed.

Under Clause 17, the author states that the consumption in the pressure circuit of single-phase meters should not exceed two watts, and for continuous-current meters seven watts at the declared pressure; it is not clear whether these figures are per 100 volts, or refer to the total voltage, whatever this may be. The specification calls for four watts for each 100 volts of pressure; this appears to be too high, and I suggest that two watts per 100 volts of pressure is sufficient for both alternating-current and continuous-current meters. In Clause 20 I agree with the author that the stipulation as to accuracy is too clumsy for ordinary use. The usual requirement for meters is an accuracy of $2\frac{1}{2}$ per cent up or down from full load to $\frac{1}{10}$ th load. This is perhaps too rigorous for small meters, and I suggest that an accuracy of within 2 per cent up or down from full load to $\frac{1}{10}$ th load for meters of 10-amperes capacity and upwards, and from full load to $\frac{1}{10}$ th load for meters below 10 amperes' capacity, should meet the case satisfactorily. I cannot quite understand why continuous-current amperes-per-hour meters only be required to have an accuracy of within 2 per cent down to the limit of $\frac{1}{2}$ ampere. This limit is certainly too high for some sizes and too low for others. As regards Clause 27, it is not clear if this allow-

able 2 per cent error is to be in addition to the ordinary 2 per cent allowable inaccuracy. I consider that meters should be accurate within 2 per cent up or down for any power factor between unity and 0.25, and this should be the total allowable inaccuracy from whatever cause.

Mr. E. FAWSETT: I find myself in complete agreement with the author in his contention that this specification does not go far enough. It ought to exclude from compliance all but the very best practice; but although I have had a copy for several years, we have always asked for and been able to obtain much better performance in several respects than is necessary merely to comply with the terms of this standard. The proposed alteration to Clause 2 is good; some makers' sizes go up in steps of 40 amperes, which is a needless complication; all good modern meters have a wide range of accurate registration, so there is no need for further intermediate sizes. Apparently the specification did not contemplate anything in the way of a power supply, and while I do not suggest separate treatment for alternating-current and continuous-current meters, the former certainly require several additional clauses, especially if polyphase meters are included, as I consider they should be. There is room for great improvement in the interpretation put on Clause 5 by the meter makers. The last part of Clause 9 refers to labelling as to temperature of adjustment and coefficient; so far as I know, the British Thomson-Houston Company are the only firm who do this. I note with some amusement that the author is discreetly silent on the subject; I hope to refer to this directly under Clause 28. In the author's suggestions on Clause 10 he specifies "drillings" for the label holes, which label he immediately afterwards says is too small. I certainly agree that it is; $\frac{3}{16}$ in. is a much better size, the holes being $\frac{1}{16}$ in. diameter and $2\frac{1}{2}$ in. apart. Clauses 12 and 13 if taken together would in a large power meter require eight separate indices besides testing dials. Such a number is, I think, unnecessary, and tends to wrong readings. I suggest a table of dial constants for large powers somewhat as follows (we attain full loads of over 10,000 kw. on a single meter already, and this specification ought to look ahead):—

	Full Load in Kilowatts	Value of 1st Index	K
Not exceeding	200	1 unit	1
Above 200, not exceeding	1,000	10 units	10
" 1,000, "	10,000	100 "	100
Over	10,000	1,000 "	1,000

On very large power meters the unit dial, if there were one, would travel faster than the disc and be a needless source of friction. I would not specify testing dials for large meters above the author's suggestions for 200 kw., as Clause 9, Sub-section 6, provides the necessary information. The author's additions to Clause 16 are excellent, although I would not go below one-tenth of a volt for large sizes as he proposes. Of course the figure of 15 watts in the specification does not take into consideration large meters; more than that is necessary and, moreover, is absolutely insignificant. Consider a 2,000-ampere 240-volt continuous-current shunted meter; on full load with a shunt drop (main circuit) of 0.1 volt, the energy loss is only 4 ten-thousandths of that recorded by the meter, and is small

Mr.
Chattock.

Mr.
Fawcett.

even compared with the probable improvement in accuracy over using, say, half that drop; at quarter load it would only be 1 ten-thousandth of the recorded load. Clauses 19 and 20 are both too lax for the present day, and I think the author's suggestions meet the case, though I consider the lower limit in Clause 20 might be less. I would make it read as follows: "The error of a meter . . . shall not exceed 2 per cent between full and one-twentieth loads, except that meters below 5 amperes capacity shall not be required to conform to this below 0.25 ampere." I think Mr. Holden's suggestion for alteration of Clauses 25-27 is rather too favourable to the manufacturers. Behaviour under pressure and frequency changes is a question of design rather than adjustment, whereas the ordinary accuracy test depends on adjustment, so that I think the word "cause" should stand.

Clause 28 makes a half-hearted attempt to deal with temperature. These are the most serious errors in many types of meter, and the least often tested for, or indeed realized by many. In an ordinary house in winter, temperatures ranging from 40° F. in the cellar to 90° fairly high up on the kitchen wall are quite ordinary, and both these places are quite usual positions for meters. All the alternating-current meters which I have examined are fairly good on this score, but most continuous-current meters are very bad. I have included a small table

instruments are far better in this respect, so the problem ought not to be insoluble. As a fillip to the makers I suggest that Clause 28 should read "A variation of 10 degrees F. above or below the standard temperature shall not cause an error in respect of such variation of more than 1 per cent."

Mr.
Fawcett.

To include polyphase meters and provide against some of their special sources of error some new clauses are necessary, and I suggest something on these lines: "A meter intended to measure true power in a polyphase circuit shall be constructed on the 'two-wattmeter' principle, and shall not show a greater divergence than 1 per cent on reversing the direction of both the current and pressure in either or both elements, and no more than 3 per cent change between 0.5 polyphase power factor, current leading, and current lagging. Pressure transformers for use with such meters must, when supplied within 10 per cent of their rated voltage and at the correct frequency give a ratio, when loaded with the meters, not differing more than $\frac{1}{4}$ per cent from the correct ratio. Under such conditions the phase angle must not exceed one-tenth of a degree. Current transformers for use with such meters must, when loaded with the meters, and at the correct frequency, maintain their correct ratio to one-tenth of full load within 1 per cent, and to one-twentieth of full load within 2 per cent, and the phase angle shall not exceed 1 degree from full load to one-tenth load, nor vary more than 1 degree between full load and one-twentieth of full load.

Dr. C. C. GARRARD: I consider that it is of the utmost importance that the specifications issued by the Engineering Standards Committee should be thoroughly discussed. I have found the specifications of the greatest use, and anything that can make them more widely known and used is to be welcomed. The meter specification under discussion is priced at 5s. per copy, and the words "copyright, all rights reserved" are printed on the cover. Mr. Holden's suggestion that copies of the specification should be sent out with tenders is excellent, but the price of 5s. per copy is prohibitive. I moreover cannot see the object of such a price, as the printing of the specification cannot cost that sum, and I do not understand why the right of duplication is withheld, as the whole object of issuing the specifications is to make them as widely known as possible. Would it not be possible for the Engineering Standards Committee to give permission, on application, to make printed copies of the specifications, so that any manufacturer may prepare copies in the style that best suits himself?

Dr.
Garrard.

I am in general agreement with the alterations to the standard specification suggested by Mr. Holden, but I should like to make several remarks and further suggestions in connection therewith. As regards Clause 2, I prefer a $2\frac{1}{2}$ -ampere size instead of a 3-ampere size for both continuous current and alternating current, as it is exactly half the capacity of the next larger size, and it is very convenient to have this exact relationship. The 75-ampere size might well be deleted, and I do not consider it necessary to have both a 250-ampere and a 300-ampere size. With regard to cases, iron has the great advantage that it magnetically shields the interior. Mention has been made in the discussion of a cast-iron case meter which developed a 16 per cent error due to a short-circuit passing through

Letter	Type	Temp. Coeff. (Fahr.)	Degrees Fahr. for 1% change	If Correct at 60° F	
				Registration at 43°	90
A	A.C. Watt-hour (Induction)	-0.06	10.7	98.8	101.8
B	C.C. Watt-hour (Commutator)	-0.25	4	95	107.5
C	C.C. Watt-hour (Mercury shunted 800 amp.)	+0.15	6.7	103	95.5
D	C.C. Ampere-hour (Mercury 3 amp.)	-0.103	5.2	96.1	105.8
E	C.C. Ampere-hour (Mercury 10 amp.)	-0.166	6	96.7	105.0
F	C.C. Ampere-hour (Mercury 50 amp. shun- ted)	-0.082	12.2	98.4	102.4
G	C.C. Ampere-hour (shunted com- mutator)	+0.142	7	102.8	95.7

showing what these mean, and as an example let us suppose a mercury meter is fixed to check a commutator meter (ampere-hour in both cases), both being correct at 60° F. in the test room. In the consumer's cellar the commutator meter then appears to be 6 per cent fast, but in his kitchen 93 per cent slow. A reasonably close guarantee for temperature would debar from compliance nine-tenths of the continuous-current meters in use to-day, but yet something ought to be done or electrical engineers must admit that, after all, our cherished accuracy of measurement is no better than that of the gas meter. Indicating

it. This must have been a very bad type of meter indeed, and this instance does not alter the fact that, other things being equal, an iron case does act as a magnetic shield. I think, however, it would be bad to exclude all other cases, for example, those of aluminium. These have the advantage of lightness, which is of great importance in the export trade. As regards Clause 6, I agree as to the provision of the two clamping screws, and do not consider sweating sockets an advantage. Mr. Holden suggests (Clause 10) that the meter cases should be sent out with two holes drilled in them to take the rivets for the name plate; would these not allow the admission of dirt? I also agree with Mr. Holden's recommendation as regards the provision of springing figures on the cyclometer dial. Under Clause 12, Mr. Holden objects to the use of the word "unit," but I would point out that the meaning is clearly given on page 4 of the specification under "definitions." Moreover, I think the word "unit" is more easily understood by the general public than the words "kilowatt-hour." In Clause 3 of the specification, as now worded, it is only required to state the temperature coefficient of the meter "if necessary." I suggest that these two words be left out on account of vagueness. It is quite possible that the manufacturer of a meter having a large temperature error may not think it necessary to advertise this fact on the front of the meter, whereas it is quite possible that the purchaser may have a contrary opinion.

Mr. Chattock has suggested that manufacturers should be called upon to guarantee meters for five years. I must express strong disagreement with this. In the first place it is no additional safeguard to the purchaser, as a motor or clock meter which will work well for one year will certainly, with proper attention, last ten years or longer. A five years' guarantee may mean either a very large expense to the manufacturer or a very small one, depending upon the care taken with the meter and the reasonableness of the user or supply authority. In any case it is something which cannot be accurately evaluated. In the long run the manufacturer would have to cover himself by considerably increasing the price. It is well known that during maintenance periods manufacturers are often called upon by unreasonable users to carry out work and incur expense which are not within the terms of the guarantee, and the manufacturer will often do this rather than incur the odium of defending his just rights. I regard the demand for a five years' guarantee for meters really as an absurdity and as being of no real value whatever to the purchaser, and I would strongly oppose it. With regard to current transformers, which have been mentioned in the discussion, I suggest that the maximum phase error allowed should not exceed one-half of one degree.

The most serious blemish of the present specification, in my view, is Clause 18, which fixes the insulation test. In the first place the application of a continuous-current voltage of between 1,000 and 1,500 volts as called for, is not very convenient. Moreover, merely to fix a minimum insulation resistance is not sufficient. The only satisfactory method of test is to apply an alternating-current voltage of the required value. No doubt for small house-service meters on consumers' premises a test pressure of 1,000 volts (continuous current) is in many cases enough. When one comes, however, to large sizes, which are nowadays frequently installed on switchboards

belonging to large consumers, instead of the so-called switchboard type, and where the working voltage is very likely between 400 and 500 volts, it is not sufficient. As, moreover, it does not cost materially more to insulate a meter as I suggest than for the lower test pressure, all should be made alike. The clause as altered according to my suggestion would read: "The insulation resistance between all the electric circuits . . . and the case should be tested by the application of 2,000 volts (r.m.s.) alternating-current pressure, having a sine-wave shape, for a period of 15 minutes without any sign of breakdown." The corresponding test pressure between the main circuit and the pressure circuit to be 500 volts (alternating current). Mr. Holden further suggests that the standard sizes should be extended to 500 amperes. In many cases such large meters would be worked by current transformers. This being so, it would be necessary to specify the amount of the secondary current, as has been done by the Standards Committee in the case of ammeters.

Mr. W. Lawton: Undoubtedly the weakest feature of the existing specification is in the two clauses Nos. 31 and 32 covering latent defects and impaired accuracy. The prevalent impression that electricity meters are an unreliable class of instrument is attributable partly to the influence of these clauses. They have also presented a low standard of service requirements to manufacturers, who, in consequence, have concentrated their efforts on minor and sometimes negligible improvements in performance under test. Those guarantees are of the utmost importance to consumers and supply authorities, and in the case of the former it is specially desirable for the avoidance of disputes that they should have confidence established in the meters registering their supply. Accuracy in a meter can easily be ascertained, but supply authorities are at a disadvantage in estimating its probable reliability. The strength of guarantees is a direct measure of the faith held by a manufacturer in his own productions, and for the protection of buyers rigorous guarantees should be specified. With regard to Clause 9, I suggest that all meters conforming to the British Standard Specification should have the words "British Standard Meter" engraved on the maker's label. I object to Mr. Holden's suggestion that in the case of "jump" cyclometer-type dials the first dial denoting units should move at a uniform speed, as such an arrangement would lead to errors of reading. I may mention the case of a meter that has registered 99 units and has very closely approached the 100 figure. The 9 on the units dial will have practically disappeared, whilst the 0 would be in full view so that the reading will appear to be 90, or 10 units below the actual. I doubt the advisability of substituting the expression "kilowatt-hour" for "unit." The latter expression has now passed into the language and any effort to dislodge it will in all probability suffer the same fate as all other attempts at altering popular nomenclature. With regard to the allowable drop in 2½- or 3-ampere meters, I consider the 2-volt limit as now specified should stand. My experience with 1,000 meters having about a 2-volt drop is that it does not seriously affect the consumer's voltage. In respect to watts lost, as the average load on a 3-ampere meter amounts to only about 1 ampere, the watts lost come to about one-third of one per cent, which is not a serious matter in a quarterly account of, say, 12s.

Dr.
Garrard.

Mr. Lawton.

r. Lawson. The specification for testing requirements of polyphase meters is a matter of considerable difficulty, but I suggest the following: Meters intended for use on polyphase circuits, whether for balanced or unbalanced loads, and where the neutral point is not available, should be constructed on the principle of the two-wattmeter method of measuring polyphase energy. Where the neutral point is available and current is to be taken between the neutral and any of the lines, meters should be constructed on the three-wattmeter method. This latter is absolutely necessary in the case of induction meters operated by transformers. The meter should be composed of single-phase elements magnetically isolated from each other so that there is no interaction between them. Each element should be adjustable to read correctly between 2½ per cent plus or minus at all loads, from full load down to one-twentieth load (watts), and at all power factors from unity down to 0.25. When tested on polyphase current, the meter should be correct within 2½ per cent plus or minus from full load down to one-twentieth load (watts), at all power factors from unity down to 0.5. In the case of 2-phase 3- or 4-wire and of 3-phase 4-wire meters, a test down to 0.5 power factor would be sufficient for both the single-phase and 3-phase tests. All tests should be carried out in conjunction with current transformers if such are used to operate the meters. The use of balanced-load meters should be prohibited for consumers' supply.

r. Shaw. Mr. C. M. SHAW: I am doubtful whether the efforts of the Engineering Standards Committee are so beneficial as one could wish. The present paper offers an opening to broaden the work of standardizing meter practice. Having had the benefit of investigating many of the finest organizations, large and small, in America, I was particularly impressed with the superior methods of maintaining meters after purchase, which is more important than quibbling about refinement of design. All seem to work on common lines without duplication. This is due in a large measure to their adopting a Meter Code, and I cannot do better than read abstracts from the preface of this publication:—

"It was the ambition of the associations to produce a reliable and up-to-date manual covering the many phases of electric meter practice as encountered by all companies, both large and small. It was the committee's belief that such a code if intelligently prepared would prove of great value, not alone to those actively engaged in operating meters but also to those interested in the practice of metering from other standpoints, namely, official, legal, etc. There was also found an urgent need of a closer agreement between the manufacturers and the operating companies as to reasonable and satisfactory specifications covering operating and design. The development of such a code with the collecting of the very large amount of data was placed in the hands of the Electrical Testing Laboratories of New York. As a means of increasing the strength and support of the work, and at the same time avoiding duplication of effort along similar lines, many associations joined hands for the further development of the code. It is hoped that it may find its place amongst the reliable books of reference in the hands of those responsible for and interested in the purchase, installation, and operation of electric meters. Whilst the code is naturally based upon scientific and technical principles,

the commercial side of metering has been constantly kept in mind as of great importance."

An active and representative committee of operating engineers and representatives of makers and testing institutions have the duty of considering developments in all branches of meter practice, and a report is presented by a chairman to the various bodies each year. This report often provides matter for keen discussion at association meetings, and any improvements after general approval are then incorporated in the code, thus bringing it up to date each year. I cannot but think we could co-operate on similar lines to the benefit of all concerned. Personally I have obtained much benefit by following the procedure set out in this meter manual.

Mr. A. E. JERSON: While agreeing with many of the points brought forward by the author, I should like to point out to him that many of his suggestions do not take into account the numerous meters of large size which are at present supplied. With regard to Clause 2, probably the 2½-ampere size is preferable to the 3-ampere size, but if it is proposed to make it standard for single-phase meters, then it should be made standard for continuous-current meters. I think the 75-ampere size should stand, for on a 200-volt continuous-current circuit this equals 15 kw., which is a very handy size, and on a three-phase circuit with a line pressure of about 400 volts it is approximately equal to 50 k.v.a., which is also a convenient size. I agree with Mr. Melsom that if sizes are to be specified, then standard sizes should be given for meters up to, say, 10,000 amperes. With regard to Clause 3, I think the suggestion of the author is rather unfortunate. His statement that cases of soft metal or sheet joined together are not used on the highest class of meters will be hard to uphold, for in the single-phase meters made by the British Westinghouse Company, the British Thomson-Houston Company, and the Aron Electricity Meter Company, aluminium cases are used, which can be described as soft metal. Aluminium cases have been found to withstand all sorts of climates and all conditions of humidity, and, further, when they are pressed in one piece they are quite strong enough for the ordinary usage to which meters are subjected. With regard to cases of sheet joined together, those used on the clock-type and polyphase induction meters are found to be quite satisfactory, and I think this is a question which should be left entirely to the manufacturers and their customers. A cast-iron cover is inclined to give a false sense of security, for any meter containing magnets, even though shielded by a cast-iron cover, can be affected by stray fields if the latter are strong enough.

Clause 6.—The proposal to have two clamping screws may be all right on the smaller sizes, but I am of the opinion that for the large sizes the clamping of screws on to a cable is quite unsatisfactory if sweating thimbles are not used.

Clause 10.—I think this clause might very well be deleted, for various customers require various particulars on the labels of their meters. With regard to riveting the labels on the covers, I think this is not quite satisfactory, as many corporations are averse to breaking the seals on meters until the guarantee period is past, and it is not always convenient to send the labels to the works to be fixed.

Clause 11.—This does not seem to allow the ordinary slow-moving roller type of cyclometer dial to be used, but

Mr. Shaw.

Mr. Jerson.

Jepson. I must say there is a considerable demand for this type of counter, particularly by the smaller Corporations. There is not much doubt in this type as to which of the two figures is to be read, and I am afraid that if this clause is made to exclude such types, many Corporations will not use the standard specification when sending out inquiries for meters.

Clause 12.—I am of the opinion that the expression "units" is better than "kilowatt-hours" for the same reason as that mentioned by Mr. Lawson. We are so used to the word "unit," and the consumer is also so used to it, that confusion would be sure to arise if the word "kilowatt-hour" is substituted. In the case of very large meters it is very often the case that the last dial reads in tens or even in hundreds of units, and consequently the alteration to the clause might have included sizes above 200 units per hour.

Clause 16.—This is not very applicable to large meters, particularly of the shunted type, for the loss considerably exceeds 15 watts. The question of pressure-drop is rather important, for meters of the commutator type require at least 1 volt drop, and if a maximum of 0.75 volt were specified, then radical alterations would have to be made to the design of meters of this type. For meters above the 150-ampere size no particular figures are specified for the pressure drop, but in the case of shunted clock-type meters at least 0.2 volt is required.

Clause 17.—With regard to the consumption of energy allowed by this clause, a distinction should be made between alternating-current and continuous-current meters, and it will probably be better to state the watts loss per 100 volts instead of taking the figure of 7 watts for a maximum of 650 volts.

With regard to the suggestion *re* a test with varying waveform, I agree with Mr. Melsom that instead of inserting Mr. Holden's suggestion about the variation of waveform of 10 per cent from a true sine curve at any point, it would be better to specify that the meter shall not vary more than 1 per cent when the supply is varied "n" per cent in frequency when using the true sine wave. With regard to Mr. Lawson's suggestions *re* 4-wire meters for three-phase working, his proposed specification does not allow the use of two elements with three current windings, and as this particular type has quite a large field of usefulness, I think it would be better to include it if a clause is inserted dealing with polyphase meters.

Mr. S. JAMES: I should like to endorse the author's remarks with reference to standard sizes. There is no advantage to be gained by having a large number of standard sizes, but there is a decided advantage in favour of a small number, both from a manufacturer's and from a user's point of view. The great thing is to decide what sizes are really necessary and then to work to them. American standards differ from German standards, and both are different from the British Standard Specification. All are to be obtained in this country, and there are at least 20 so-called standards to be obtained below 100 amperes; an unnecessarily large number. I agree with the author that a 2½-ampere meter is to be preferred to a 3-ampere, at any rate for alternating-current meters, because a standard set of gears to fit 2½, 5, and 10-ampere meters, all running at standard speed will also fit 25, 50, and 100-ampere meters with no alteration except a change of dial. The dials for

the last three, of course, read ten times as much as the first Mr. James. A 75-ampere meter is quite unnecessary, just as unnecessary in fact as a 7½-ampere meter between the 5- and 10-ampere sizes. With regard to the additional standard sizes suggested by the author, I venture to say that the 150-ampere and 250-ampere meters are unnecessary, there being an ample range with 100, 200, 300, 400, and 500 amperes.

Clause 6 in the specification deals with the terminal compartment. The latter portion of the clause evidently refers to watt-hour meters, and the wording suggests a three-terminal connection. This method of connection is out of date and is considered bad practice by most engineers, although some still profess a liking for it. The chief objections to it are that by breaking off the potential lead the registration of the meter is interrupted, although the consumer still obtains a supply of current. It is not a difficult matter to arrange that the meter shall be registering when a visit from the meter inspector is expected, and fraudulent practice may go for a long time undetected. Further, by inserting a wire in the fourth terminal which is provided for testing purposes, current may be obtained without being metered. I suggest, therefore, that the second part of Clause 6 be altered to read: "Watt-hour meters or meters having a pressure circuit shall have the terminals adapted for both the mains to pass through the meter." This would prevent the meter being tampered with as suggested above, and has the further advantage that a joint on to the main which does not pass through the meter in the three-terminal method is unnecessary. A uniform method of connection would be an advantage, and I suggest (1) that bottom terminals only be recognized; (2) that the main terminals should be on the left and the consumer's terminals on the right-hand side. With a standard method of connection there would be less chance of a meter-fixer making a wrong connection. Clause 9, sub-section 6, says the meter shall bear a label marked with the speed of the rotor in revolutions per minute at full load and at the standard temperature, or at the option of the manufacturer the number of revolutions of the rotor in registering one unit. The latter method is to be preferred, and if universally employed would considerably simplify meter testing.

Clause 23 specifies that the meter shall not be injured and its accuracy shall not be permanently impaired by passing for a period not exceeding half a second a current in the main circuit not exceeding 30 times the capacity of the meter. This is a difficult test to carry out satisfactorily for obvious reasons, and I suggest the following as being more practical: "The meter shall not be injured and its accuracy shall not be permanently impaired by direct connection across the mains through a fuse of double the rated capacity of the meter." This test approaches more nearly to service conditions than the specification test.

The author suggests the use of the expression "kilowatt-hour" instead of "unit." I should like to endorse that. "Kilowatt-hour" is understood all over the world and "unit" is not. Some countries importing British meters do not recognize the term "unit" or "Board of Trade unit," and the Board of Trade is unknown. The average consumer in this country would be just as contented if his meter was marked "kilowatt-hours." He does not know what a unit represents, except that it is that for what he pays 6d. or whatever price it may be

Mr. G. KAPP: I should like to point out that there is a difference in the working conditions between a meter tested in the laboratory and the same meter in regular service on a consumer's premises. This difference is recognized by the German rules, which allow a greater error in the latter case. In the standard specification discussed by the author it is not stated whether the permissible error refers to laboratory tests or to the commercial use of meters. I think that the important point is the performance of the meter in actual service; for this reason meters should be tested *in situ*. In view of the disturbing influences, such as temperature variation, vibration, moisture, etc., to which meters may be subjected when in commercial use, it would be justifiable to have two scales of permissible percentage error; at any rate it would be necessary to state whether the scale given in the specification and the amendments suggested by the author refer to laboratory tests or to the working conditions of the meter. I hope the author will make a definite statement on this point in his reply.

Mr. A. M. TAYLOR: I wish to refer to the use of instruments on high-tension alternating-current three-phase switchboards, viz. to those on the generators and on the outgoing feeders. In the case of the generator meters the points to be guarded against are errors introduced by the loads on the three phases not being equally balanced, also those due to the varying power factors of the load. In the case of the instruments on the feeders there is the error introduced by the insertion of relays, ammeters, power-factor indicators and, occasionally, "trip" coils in the secondary circuit of the current transformers. This changes the ratio of the transformer, and thereby introduces errors. Without pretending to offer more than a suggestion as to how these errors should be guarded against, I wish to put forward the following clauses for consideration: (1) The accuracy of the meter must not be affected by the load being unbalanced, provided that the load on no individual phase differs by more than 20 per cent from that in either of the other phases. (2) The meter must be suitable for working with any other apparatus supplied from the same current transformers, and with this object the meter shall be tested in conjunction with the current and potential transformers with which it is to be used, and the limits of accuracy determined upon shall be understood to embrace the errors introduced by a 2 per cent change in the ratio (see Clause 3, following) of the current transformer to be employed. (3) The current transformers that are to be used shall have a change of ratio which is not more than 2 per cent over the normal range of load, and this must include errors caused by the use of protective relay coils (exclusive of "trip" coils) or ammeters or power-factor meters having small values of impedance. If trip coils are used, the change of ratio should still not exceed 3 per cent. (4) The accuracy of the meter must not be affected by the power factor of the load within the limits of unity and 0.6. The errors in the meter itself, due to the interaction between the elements, and the difficulty of testing the elements by means of single-phase coils independently of one another, have already been dealt with by another speaker, and I am substantially in accordance with his recommendations.

Mr. H. A. RATCLIFF (*communicated*): The author's criticisms and suggestions are very reasonable, and with

most of them I am in complete agreement. The specification in its present form does not protect the purchasers of meters to a sufficient extent, and in fact it may possibly have the contrary effect, since there are on the market many meters which would comply with the requirements of the specification and which are nevertheless thoroughly unreliable. It is perhaps rather questionable whether a specification drawn up by a committee essentially representative of many varied interests can ever be very exacting in its requirements, and for this reason matters of technical detail will probably always have to be left to individual specifications based upon actual experience of the good and bad features of a large variety of meters. A good specification should be as widely applicable as possible to all well-made meters having an established reputation, and it should above all things be free from unreasonable fads. It must, however, rigorously exclude the cheap and inferior meters mentioned by the author. The useful purpose of such meters is not quite apparent. The following notes deal with several clauses of the specification in addition to those criticized by the author. The specification covers both continuous-current and alternating-current single-phase meters, and under "Standards and Definitions" it states that the British Standards of Electrical Quantities shall be the legal standards in the custody of the Board of Trade. So far as I am aware, there is no legal standard of electrical power as distinguished from the mere product of volt and ampere measurements, which is obviously inapplicable to the requirements of several clauses in the specification. A footnote refers to the use of a suitable wattmeter, but it is very doubtful whether at the time the specification was drafted the Board of Trade possessed such an instrument, and even at the present time it is extremely difficult to say what may be regarded as a really reliable standard, although much valuable work by Messrs. Rayner and Paterson at the National Physical Laboratory has materially advanced the establishment of such a standard.

Clause 1 leaves much to individual interpretation and judgment. With regard to Clause 2, I agree with the author that the $2\frac{1}{2}$ -ampere size is preferable to the 3-ampere size for single-phase meters, and I would also suggest this size for continuous-current meters; 75 amperes is an unnecessary size, and probably also 150 and 250 amperes. Experience has shown the following to be useful— $2\frac{1}{2}$, 5, 10, 25, 50, 100, 200, 300, 500, and 1,000 amperes.

Clause 3.—Unfortunately cases of soft metal or of sheet joined together are used on some of the highest class of meters. For small meters cast-iron cases are probably most suitable, but the weight is almost prohibitive for large sizes, and owing to the size of the dies, pressed steel covers are likely to be expensive. It has yet to be seen whether pressed steel withstands rust satisfactorily, and in any case, as frequent revision of the specification is recommended, the suggested amendment to this clause might well stand over. A thoroughly satisfactory covering material applicable to all types of meters has yet to be produced.

Clause 5.—Presumably the customer may have the meters painted how he likes, provided always that the cost of any extra work is included in the price paid for the meters.

Clause 6.—In its present form this clause possesses no

practical value. Terminal boxes are as a rule the worst feature of many meters, particularly so in the case of those of Continental origin. The current-carrying capacity of the terminals and connections is apparently worked out to the fourth decimal place, but with an absolute disregard of mechanical requirements and considerations of safety. Much detail requires to be specified in order to obtain satisfactory terminal boxes. The author's suggestions are in accordance with sound practice, but I would recommend that in all sizes above 100 amperes sweating lugs should be provided for the reception of the cables, and that in the case of 500-ampere and larger sizes suitable set screws be provided in the lugs for gripping the cables in addition to the solder.

Clause 7.—The value of the manufacturer's seal is questionable.

Clause 8.—Not always convenient.

Clause 9. *Sub-section 6.*—This requirement is unnecessary and not always possible. It also does away with the advantage of adjustment by means of change wheels giving different constants.

Clause 10.—The requirements of this clause are altogether unreasonable and impracticable. The author's suggestion for the use of rivets is good, and I am pleased to note that he considers the size of plate to be too small. Not only is it too small, but it is also too thin, as these flimsy plates rot away in a very short time. Extensive experience has shown that the most satisfactory plates are those made of cast brass.

Clause 11.—This apparently allows the use of cyclo-meter counters, which are notoriously unreliable. The author's suggestion is very sound and reasonable, but I would go further and suggest that the old fashion clock-dials are the only ones worth serious consideration. Difficulty of reading is no valid objection to their use, since a person incapable of reading them correctly has no business to be reading electricity meters.

Clause 12.—It is a very debatable point as to what should be provided in the way of registering and testing dials, and requirements must necessarily vary somewhat, depending upon the size of the meters, or as the author calls it "the kilowatt-hour per hour capacity." (Why not kilowatt capacity?) The testing dial on a 200-kw. meter appears to be quite unnecessary, and in fact the unit-per-division dial is of doubtful utility on meters above 100-kw. capacity, unless provided purely for testing purposes.

Clause 14.—The permissible speed is rather on the high side. A speed of 100 revs. per min. for continuous current and 50 revs. per min. for alternating-current meters is not an unreasonable restriction.

Clause 15.—A maximum permissible temperature rise might be specified.

Clause 16.—I fully agree with the author's suggested amendments. The 15-watt loss is very high, whereas his figures show only a 10-watt loss, which is more in accordance with the requirements of at least one well-known specification. A maximum pressure drop of 0.5 volt will probably be found sufficient in the case of all high-grade ampere-hour meters; watt-hour meters of small capacity appear to require a pressure drop comparable with that obtained in electrolytic meters.

Clause 17.—I agree with the author that the permissible

shunt loss is far too high. Reasonable values would Mr. Ratcliff, probably be two watts per 100 volts for continuous-current meters, and one watt per 100 volts for alternating-current meters.

Clause 18.—This might be modified with advantage. In its present form it appears to necessitate the use of one specialized piece of apparatus.

Clause 20.—The author's criticism is well merited, but I cannot quite agree with him regarding the request for accuracy at low loads below $\frac{1}{2}$ ampere. Experience has shown that $2\frac{1}{2}$ -ampere-hour meters when new can be made correct within $3\frac{1}{2}$ per cent at one-tenth load, and 5 per cent at one-twentieth load; and it is therefore reasonable to specify such a maximum limit of error, particularly as these small meters are only used for a not very remunerative class of consumer. The importance of high initial accuracy cannot be over-estimated, as the error is bound to increase with time, and therefore the less serious will it be if the original permissible limits have been close. It is very unfortunate in this respect that the Board of Trade have recently extended the limits of permissible error, and as a result many inferior meters will now satisfactorily pass the test requirements.

Clause 23.—The test specified is designated "Short-circuit Test." Thirty times full load is a very good momentary overload test for a meter, but it is certainly not a short-circuit test, and must not for a moment be confused with what is a really severe test which very few meters can successfully withstand.

I agree with the author that Clauses 25, 26, and 27 are rather vague, but I hardly consider that his proposed amendment much improves matters. Undoubtedly the errors under consideration are those in respect of such variations, and are not to be confused with errors existing under conditions other than those arising from the variations in question. Probably instead of the words "an error" the expression "a change in the rate of registration" would be more suitable.

Variations of wave-form.—This is only of importance in the case of meters of the induction type. The percentage departure from a true sine wave is not very definite, since it is the amplitude and frequency of the predominating harmonic which affects the accuracy of the meters. If possible, therefore, a knowledge of the most pronounced harmonic is essential, and also an approximate value for its maximum percentage amplitude. The effect of the third harmonic, for instance, can be roughly ascertained by testing the meter on a circuit of three times the normal frequency, afterwards making allowance for the amplitude of such harmonic when superimposed on the fundamental sine wave. The incompleteness of the specification appears to have been realized at the last moment, hence the footnote referring to the Appendix, which has not yet appeared, although intended to deal with some of the most technical features covered by the specification.

Mr. M. OSBORNE (*communicated*): Mr. Ratcliff has Mr. Osborne, pointed out that the errors in electricity meters are continually increasing; the chief factor of the errors, in my opinion, is due to the "sapphire jewel bearings" wearing, after being in use a comparatively short time. I mean by this that the originally high polish of the sapphire becomes rough, which of course sets up friction. The bearing troubles form the most serious faults to which modern

meters are liable, and the only way to obviate these troubles is by the adoption of diamonds for jewel bearings. Mr. Chattock suggested that the meter manufacturers should give a five years' guarantee with their meters. This, I contend, would only be possible by the substitution of diamonds for sapphires as the jewel bearings, because the polished surface of the sapphire wears much more than many supply engineers realize, and after two or three years in service the polish becomes somewhat rough; under this condition one cannot expect the same degree of accuracy as when the meter was first installed. Moreover, as this roughness grows gradually, it must mean a considerable loss of revenue to the electricity supply authority. The diamond after being in use for at least seven to ten years will give, owing to its much harder qualities, the same degree of accuracy as initially. Whilst admitting that the use of diamonds would add to the cost of the meters, I have made some inquiries of a Birmingham firm of jewel makers, and find that the extra cost would be comparatively small compared with the advantages gained. I am sure the results would justify the change, for in addition to the sustained accuracy of the diamond, the repairs necessary with the sapphire are eliminated, and a substantial reduction in the maintenance of the jewels is obtained. I suggest that the substitution of diamonds for sapphires for jewel bearings in electricity meters be embodied in the new British Standard Specification.

Mr. A. P. YOUNG (communicated): I think it is generally admitted that the British Standard Specification No. 37, published in 1907, inadequately serves the purposes for which it was presumably compiled, due chiefly to the fact that in its present form it is not applicable to some of the numerous types of meters now used for the metering of energy. The author is therefore doing a service in bringing forward this paper with a view to stimulating a general discussion of the whole question, and thereby urging the Engineering Standards Committee to prepare a revised specification. The proposed method of modifying the specification clause by clause as outlined in his paper does not, however, seem to meet the requirements of the case exactly. In the first place I would suggest that two specifications be prepared, one for continuous-current meters, and the other for alternating-current meters. This seems very desirable in view of the fact that the various types of meters for the two classes of service are of entirely different construction, with the result that their general characteristics are also different. In addition, each specification should be divided into sections, so that meters belonging to any particular class can be treated separately. That is, it might be found advisable to divide the continuous-current specification into two parts, the first dealing with the ampere-hour type of meters, and the second with the watt-hour type of meters. In the case of the specification for alternating-current meters, single-phase meters should be treated separately from polyphase meters, and then there should be a further section relating to meters operating in conjunction with current transformers. Also in each case it seems necessary that some distinction should be made between meters of the house-service type and those designed for switchboard work. With reference to the author's suggested modifications of the various clauses in the specifications I should like to make the further comments.

Clause 6.—The author proposes to standardize certain

sizes of holes in the terminals for the various standard sizes of meters suggested under Clause 2. This does not appear to me to be a workable arrangement, for some of the sizes given are not standard drill sizes, and it is difficult to understand how he would propose to drill the holes in the terminals. Further, I should like to know whether the author seriously puts forward the suggestion that, for the high-capacity meters referred to, it makes a satisfactory arrangement to connect the incoming cables in terminal holes by means of two clamping screws, as implied by the proposed clause. I think it is a fact that most manufacturers of reputable supply cable thimbles, into which the cables are sweated for meters above 50-ampere capacity.

Clause 12.—The suggestion to use the expression "kilowatt-hour" in place of the word "unit" is, I think, not a good one. The expression "kilowatt-hour" is far too cumbersome for ordinary everyday use, and further, consumers have become so accustomed to the word "unit" that any such change as proposed by the author would certainly not meet with the approval of station engineers and meter users generally. It is quite true, however, that in other parts of the world the word "unit" as applied to electricity meters may not convey any definite idea, and as much has been heard of late regarding the use of the word "Kelvin" for the unit of electrical energy—that is, one kilowatt-hour—it would seem advisable for this aspect of the question to be considered when the specification is revised, assuming that this is eventually done.

Clause 17.—The suggestion that the consumption in the pressure circuit of a continuous-current meter for voltages up to 650 should not exceed 7 watts is to be deprecated, as I think it is generally recognized that a reliable watt-hour meter of the motor type operating on the Thomson principle cannot be constructed with such a low watt loss.

The author appears to have discreetly avoided the whole question of polyphase meters, which really stand in a class by themselves, and also that broad class comprising both single-phase and polyphase meters operating in conjunction with potential and current transformers. Leaving out the question of transformers for the time being, and considering only the question of polyphase meters, a specification dealing with these, to be complete, should standardize some system of connection. The National Physical Laboratory some two years ago, as a result of tests which they had carried out on various makes of polyphase meters, proposed a system which I believe has been adopted by most manufacturers in this country. Put briefly, the system is simply this: That considering the two phases to which the two meter elements are connected, then the arrangement must be such that the top element is inserted in the "leading" phase and the bottom element in the "lagging" phase. This seems to meet the conditions satisfactorily; but I should not only like to see some such standardization as this, but also some clear and definite explanation as to what is meant by "leading" phase and "lagging" phase respectively, as the average engineer appears to be quite ignorant on this point.

Coming to the question of meters operated in conjunction with current transformers, it does not seem to be generally recognized that in cases of this kind the governing factors, from the points of view of accuracy, are the accuracy characteristics of the transformer, as in the nature of things a meter can be constructed with a greater degree

ing of accuracy than a current transformer. In view of this, the suggestion already put forward that there should be a distinct section in the specification relating to meters operating in conjunction with current transformers seems almost necessary. The present specification makes no mention whatever of current transformers, and one can only assume that the Committee, when they drafted the specification, did not have cases of this kind in mind. It is well known that any form of induction meter, after calibration in the ordinary way, will give different results when used in conjunction with any form of current transformer, due to the fact that the ratio is not constant but slightly dependent on the load, and further because there is a very small phase angle between the primary and secondary currents which increases as the load decreases. As a matter of interest I should very much like to know if the author would be willing to accept Clause 27, relating to the error produced on varying power factor, for the case of a meter operating in conjunction with a current transformer for all loads from full-load down to one-twentieth of full-load, as is implied. Presumably the high-capacity meters referred to under Clause 2—that is, say from 200 to 500 amperes—would have to be supplied with current transformers, so apparently the author intends Clause 27 to apply to such cases. In cases where we have polyphase meters working in conjunction with current transformers, the proposition is more difficult because on a power factor of unity there is a phase displacement of 30 degrees between the current and potential in the case of each element, so that with a power factor of 0.5 this phase displacement of one element will have increased to 90 degrees. I admit that the whole question of current transformers is very complicated, but it certainly should be confronted by any Committee formed to revise the present standard specification, with a view to removing the present uncertainties that exist. An additional complication arises from the fact that the characteristics of any transformer are dependent upon the secondary load, and as in actual practice it is usual to connect instruments, trip coils, etc., in series with the meter, it is essential that the actual operating conditions should be taken into account when the meter is calibrated by the manufacturer.

The question of potential transformers is relatively simple, as these always work at a practically constant load, and they can be designed to give quite a definite ratio at this load, with a phase displacement between the primary and secondary voltages that is for all practical purposes negligible. In conclusion, I thoroughly agree with the last portion of the author's paper in which he suggests that the Institution should urge the Engineering Standards Committee to publish as soon as possible a revised and complete specification, and it would certainly be a great improvement if the price were reduced to 1s. per copy so as to induce a wider circular and more general use both by meter manufacturers, supply station engineers, and meter users generally. Should this task be undertaken, however, it is very necessary that every phase of the problem be taken into consideration with a view to producing a specification, or specifications, which apply to every possible case likely to be met with. This, in my opinion, can only be done by dividing and sub-dividing the specification in the manner indicated above, and considering each section by itself thoroughly and completely.

Mr. E. GARTON (*communicated*): Before discussing the various clauses mentioned in Mr. Holden's paper, I should like to ask if the standard specification is to be applied to house-service meters only, or whether switchboard meters are to be included. Assuming it is only to apply to the former, I would suggest that the specification be divided into two main sections, (a) for continuous current, (b) for alternating current, and again sub-divided for various types of meters, the continuous-current section being divided into ampere-hour meters and watt-hour meters, and the alternating-current section into single-phase and polyphase meters, and a third section for meters belonging to the latter classes when used with current transformers. I think this is very necessary since it is impossible to make one specification satisfactorily cover all types. In Clause 2 the author mentions meters of higher capacity than would ordinarily be used without current transformers; these in my opinion should not appear in this clause unless it is made quite clear that they are to be used in conjunction with current transformers, but I would much prefer to see them under another clause as already mentioned. This also affects Clause 20, in which it is stated that alternating-current meters can easily be made: within 2 per cent from one-twentieth full load to full load. This accuracy although easily obtained for meters without current transformers is very hard to obtain for a combination of meter and transformer, as it is impossible to construct a current transformer having the same ratio at all loads between the limits specified.

In Clause 10 reference is made to a purchaser's label, and it is mentioned that the manufacturer shall provide two holes in a suitable position for this label. Does the author intend that all meter covers should be supplied with these holes drilled? If so, I cannot agree with him, as it would necessitate undertakings not using labels plugging up these holes. It is also undesirable to ship meters with holes in the case, owing to the liability of dust entering. I quite agree, however, that the purchaser's label should be standardized, but the party who drills the holes should most certainly fix the labels.

In Clause 3 the author lays down a hard-and-fast rule that the cases should be made of cast iron or pressed steel. I cannot agree that these materials are desirable for covers, which I take it are included under this heading, as they are very liable to rust, especially in coast towns and those very humid climates of the tropics. I think it would be much better to make covers of some non-corrosive metal, such as gun-metal, zinc, or aluminium, and it is immaterial whether they are cast or pressed, as the strength of a cover is purely a question of design. Personally, I should much prefer a fairly thin pressed cover, owing to the fact that meters are sometimes dropped after they have been finally tested. Should the case be robust the effect of the fall will not be apparent, whereas with a fairly thin pressed cover it will most likely become dented or damaged in such a way that it can easily be detected, and the meter will be examined to see whether it is damaged internally, whereas the meter with the more robust cover will probably be connected in circuit on the assumption that the meter is in every respect satisfactory; I think everybody must agree that a meter should be thoroughly overhauled after it has had a fall. Another disadvantage of the cast or pressed steel cover is that it affects the

accuracy of the meter, and it is quite impossible to calibrate a meter without its cover. I have heard it said that a percentage allowance to compensate for the effect of the cover can easily be made, but this is impossible owing to the fact that the error is dependent upon the position of the magnet, and this is changed when calibrating the meter. Referring again to Clause 20, I should like to know why the author considers an alternating-current meter should have a better guarantee than a continuous-current meter. With regard to the variation of wave-form, I note that the author considers a variation of wave-form of 10 per cent from the true sine curve at any point should not increase the error of the meter by more than 1 per cent. I think this is very indefinite, owing to the difficulty of determining what is meant by a 10 per cent variation in wave-form. For instance, it might be peaked to the extent of 10 per cent, or it might have a 10 per cent dip in the top of the wave. In fact one might have a very great variety of waves each having a different effect on the accuracy of the meter, but still within the variation at any point as laid down by the author. I should be very glad if the author would give a little more information on this point, and explain just how he intends to define the 10 per cent change.

Mr. H. C. TURNER (*communicated*): Whilst thoroughly agreeing that a standard specification for electric supply meters will be a splendid thing for manufacturers, electric supply authorities, and consumers generally, if universally adopted and enforced, I should like to make one or two suggestions and criticisms of the author's paper. In the first place mere statements such as are found in Clause 2, that the $2\frac{1}{2}$ -ampere size is preferable to the 3-ampere size, and in Clause 6, that cases of soft metal or steel jointed together are not used in the best meters, give the impression that the author has a special meter in his mind to suit which he wishes to model the specification, and that wherever the said meter is well within the specified limits or characteristics he desires to cut away the fringes in order to make the specification a closer fit to his meter. This seems also very apparent in his comments under Clause 16 *re* losses and pressure drop.

Clause 2.—The author advances no reason whatever for asserting that the $2\frac{1}{2}$ -ampere size is better than the 3-ampere size, but to my mind it seems that it depends largely upon whether the full load is 2½ or 3 amperes, though from a manufacturer's point of view if a 25-ampere size is made, then the $2\frac{1}{2}$ -ampere size will be very convenient, because then the same gears will be available for both. The author then suggests the addition of some extra sizes which are called for to some extent, but entirely overlooks the fact that from the point of view of demand there is a much larger sale for a 1½-ampere meter, and also for a size intermediate between 10 and 25 amperes, nor does he state why he deems the 75-ampere size not really necessary; this, again, I think depends on the capacity of the load. I have already commented on his statement *re* Clause 3 that the highest-class meters do not possess soft metal or jointed covers, and whilst I personally agree that cast iron is unequalled for this purpose, I should like to ask how does the author set his criterion of the highest-grade meter.

Clause 6.—The author's suggestion, while probably amenable to reason from the user's point of view, would mean an extensive and expensive stock for the manufac-

turer. Surely the same size of terminal (0.32 in. if the author wishes) can be used for all sizes up to 25 amperes rather than a separate size for each? Also one size for 50, 75, and 100 amperes, and then again 0.8 in. probably for 150, 200, and 300 amperes.

With Clauses 10 and 11 and the author's comments I entirely agree, but in the case of Clause 12 I consider again that the author is making a rigorous attempt to specify one special meter. The original clause is quite ample in saying that "Any testing dials shall be differently marked from the units registration dials." The number of testing dials and the point at which to change their number are surely quite arbitrary, and need only concern the tester who has to use them.

In Clause 16 the author reveals himself as a manufacturer in that he would word the specification to coincide with what the factor is able to do rather than with what the consumer or buyer would like to demand of the meters he purchases. Thus, taking a meter for a 200-volt circuit, as at present worded the meter would use up 1 per cent of the full power which it can carry, no matter what its capacity may be; whereas the author suggests that in a $2\frac{1}{2}$ -ampere size at 200 volts the meter should be allowed to dissipate 0.375 per cent, but in a 100-ampere size only 0.05 per cent. Now, dealing in percentages only, and considering the buyer to be a practical man of no great electrical attainments, are there any grounds for assuring him that he is doing well in allowing one meter 0.375 per cent and the other 0.05 per cent? Obviously he will say, "Make them all 0.05 per cent, please," so I opine that the specification is well worded in fixing the worst condition for one as the worst condition for all and then letting the manufacturers compete for improvements and refinements on this particular basis. For it does not always follow that meter losses are absolute losses, seeing that a meter with a slightly higher loss may through that extra energy be so designed as to give a torque of such a value that it will amply repay for those losses in the return of revenue for small long-hour loads, which a meter of low losses and low torque would not record at all. The same line of argument holds good in regard to the suggestion for the alteration of Clause 17. How could a non-technical man be persuaded that he should allow greater losses in the pressure coil of a continuous-current meter than in that of an alternating-current meter; to him both are meters, and he cannot see why one should be allowed more grace than another, though we know that it is much easier in the one case than in the other to obtain these small values of watts lost. Here again I contend that the specification should state a reasonably low figure for all, and then let individual design and merit improve on this figure in the way of competition between meter and meter.

Clause 20.—The author appears anxious to narrow the limits much more, but in doing so why should he stop, seeing that several makes of alternating-current meters can be made accurate within 2 per cent between one-fortieth of full-load and 25 per cent overload? Also, seeing that alternating-current meters can be designed so that a change of temperature up or down of 18 degrees F. does not produce an error of 1 per cent, why not exact this from all meters? Certainly in some cases it would redound to the consumer's benefit, seeing that a very common type of meter, namely the mercury motor type, has a considerable

temperature coefficient and if installed in a living room would be subjected to such changes of temperature in the winter as would render it inadmissible in Clause 20 of the specification. Of course I am well aware that many of these meters are now compensated, but I think it is safe to say that the majority are not. Nor can I bring myself to agree with the author's allegation of absurdity respecting Clauses 25, 26, and 27, though I quite concur in the matter of the altered phraseology. Using the example given, a meter may be 2 per cent slow at normal voltage; and assuming that to 10 per cent variation of pressure would make the meter correct, that is would produce a 2 per cent error, then it must be remembered that by the specification meters would also have been passed which were 2 per cent fast, and that there is as much chance of these being out on circuit as there is of the slow meters, so that under the same conditions of change all these fast meters would become 4 per cent fast, whereas if the specification had been enforced this error could not have exceeded 3 per cent. For myself I should like to see inserted in the specification a limit of error for combinations of the above variations, thus—that the increase of error shall not exceed 2 per cent when with a power factor of 0.5 the normal frequency is varied to 10 per cent up or down. This is a condition which is rarely fulfilled and which would well do with attention from the manufacturers.

Variation of wave-form is the subject of the next suggestion. Here the author would specify that a variation of 10 per cent from a true sine wave at any one point shall not increase the error of the meter by more than 1 per cent. I need hardly point out that a wave-form not varying more than 10 per cent at any one point might easily produce a greater error than that mentioned, whereas a wave-form varying much more than 10 per cent might likewise easily produce an error so small that it could not be computed; so that although the author's suggestion is one way of labelling wave-forms, it is not one which entirely suits the case. For myself, and as a result of many experiments, I believe that it is sufficient to specify that a meter shall have a small variation of its constant with large variations of frequency, which is quite compatible with reason, seeing that all variations of wave-form are due to the super-position of sine waves of different frequencies, generally being harmonics of the fundamental curve. On the whole it seems wiser to attack the problem from its origin, namely, variation of frequency, rather than deal with wave-forms which are of such an elusive and variable nature, so hard to define, and so numerous in kind, that there are scarcely any two alike. Again is it not a fact that the wave-form of the pressure circuit is quite distinct from that of the series circuit by virtue of the different inductions therein? None the less, if the latest innovations of polycyclic systems are continued, it will be necessary for the manufacturers to attack this problem in real earnest. I agree with the author that the specification might easily be made to embrace polyphase meters and also prepayment and two-rate meters, and I strongly support the author's suggestion that the Institution should urge the Engineering Standards Committee to publish as soon as possible a revised and complete Standard Specification for Electric Supply Meters.

Mr. S. H. HOLDEN (in reply): As several speakers have referred to the same points, perhaps I may be allowed to

make my reply general and not refer specifically to individual speakers.

In the first place, with 1 think one exception, speakers confined themselves to a purely insular view of the subject, ignoring the advantage to British trade with foreign countries which would arise from the acceptance of a standard specification by English engineers in England and the prestige which it would thus acquire in many colonies and foreign countries. Without giving any advantage to one English manufacturer over another, English engineers should be willing to assist English manufacturers to compete in the world's markets.

Cases.—Several engineers specify a cast-iron case and nothing else; to such engineers the present Standard Specification is insufficient, and to make it acceptable to them I propose specifying the material, viz. cast iron or pressed steel. There is nothing to prevent anyone buying a cheaper form of case if desired. It is well understood that meters with iron covers must be tested with the covers on. Several speakers suggested limits of accuracy different from mine. The great thing is to have the limits simple. The suggestion of 0.25 ampere for the lower limit instead of my proposed 0.5 ampere should be accepted; and 2 per cent instead of the present 2½ per cent is also a good suggestion.

Holes in terminals.—The suggestion for sizes of holes for cables in terminals should be supplemented by a statement that all meters above 250-ampere capacity should have sockets into which the cables can be soldered. It is hoped that those speakers who disapproved of the proposed sizes will state the sizes they consider suitable.

Standard sizes.—The 300-ampere size might well be omitted. If larger sizes than 300 amperes should be specified, I would suggest 750- and 1,000-ampere.

Pressure drop.—Plenty of good meters can be obtained within the limits I suggest. It would be unwise to lower the standard for the sake of one or two makers who use a much larger pressure drop. The limits suggested were not intended to apply to meters with separate shunts, i.e. switch-board meters. If these are to be included, some modification would no doubt be necessary.

Loss in pressure circuit.—I do not at all agree to specifying this at 2 watts per 100 volts. Good alternating-current meters take only 2 watts at 500 volts single-phase, or 4 watts polyphase; and continuous-current meters are made at 7 watts for the same voltage. If the Standard Specification called for 4 watts at 500 volts, makers would soon meet that requirement.

Labels.—The suggestion that the customer's label should be settled individually is not good. The main object of the specification is to leave nothing to be settled, outside it. Let there be a standard size of label and standard drilling to fix it. The only thing then to be settled would be drilling or no drilling.

Large alternating-current meters.—All guarantees of accuracy should assume that the meter-maker also supplies the transformers, and that errors in the transformation ratio are counted as part of the meter error.

Wave-form.—As long as engineers refer to the effect of variation some limit must be fixed; any improvement on that proposed would be useful.

Temperature.—The permissible variation in speed due to temperature should be fixed, and the declaration of its

Mr. Holden.

Mr. Holden, amount would not then be necessary on the label. Mercury motor meters at present suffer from a disadvantage in this respect, but I do not consider that the Standard Specification should be framed in such a way as to relieve manufacturers of the necessity of striving after improvement.

Insulation.—The suggestion for a more severe test with alternating current is certainly good. Meters at present offer plenty of scope for improvement.

Guarantee.—Many managers of meter departments at present overhaul their meters after two or three years' service. Obviously no guarantee should extend beyond this overhaul.

Counters.—The best types of springing-figure counters leave no possibility of an error of 10 units as described. The specifications should exclude any type that has this possibility of error.

Dial marking.—"Kilowatt-hour" is well understood on the Continent and in most foreign countries. "Board of Trade unit" is not, and I believe the Board of Trade themselves object to its use upon meter dials. The term "unit" is meaningless by itself.

Clock-type meters.—I have no experience with these, so am not competent to make any suggestions. If there are special points in regard to them that require specification a suitable clause should be inserted.

External fields.—The effect of these is important, and a Mr. Holden clause defining what strength of stray field may or must not affect a meter, and to what extent, might be useful. I entirely disagree with the speaker who stated that every form of meter could be influenced to the extent of 5 or 6 per cent by stray fields. Such a meter would be a very inferior article.

Polyphase meters.—These should have the same limits of error as single-phase meters. The suggestion of a standard arrangement of terminals is most important, and, indeed, this applies to every type of meter. Why should one maker place his + terminal on the right-hand side and another maker place his on the left? And why should some terminals be at the top, others at the sides, and others at the bottom? It is to be hoped that the suggestion to include polyphase meters in the specification and to impose standard conditions of testing will be accepted by the Engineering Standards Committee.

It is understood that all tests are made in well-equipped test-rooms or laboratories and not on site. Electrolytic meters are excluded by the title of the present Standard Specification, as also are meters of the switchboard type and many other forms of meters. It might be well in the future to divide the Standard Specification into sections, each dealing with a distinct type of meter, and alter the title accordingly.

THE MAGNETIZATION OF IRON AT LOW INDUCTIONS.

By LANCELOT W. WILD, Member.

(Paper first received 14th August, and in final form 20th October, 1913.)

Although the magnetization of iron at flux densities varying from 1,000 to 20,000 has been very thoroughly investigated, experimenters have hitherto generally fought shy of carrying out investigations at very much lower flux densities. It has therefore occurred to the author that an investigation between $B = 1$ and $B = 100$ would not be wholly without interest. Tests have been carried out accordingly on two samples of transformer steel having widely different characteristics. These are known as Lohys (mild steel) and Stalloy (silicon steel) respectively.

The samples were in the form of strips measuring 7 in. \times 1 in. (1778 \times 254 cm.) and were built up into magnetic squares of the form shown in Fig. 1, alternate layers being arranged so as to break joint. The squares were built up in fibre bobbins permanently fixed to a base-board. These bobbins were evenly wound with 220 turns of No. 14, 220 turns of No. 20, and 4,400 turns of No. 28 double-cotton-covered copper wire. This last winding was divided into 4 equal sections, which could be arranged in series or parallel, so that all 4 sides of the square were equally loaded.

All the above windings were used as secondaries. In

addition a primary winding was put on consisting of 4 turns only, one turn being on each side of the square. The leads from the primary winding were twisted together and led away to a reversing switch at a considerable distance.

The board on which the coils were fixed was placed on a plush mat and was so tilted as to ensure that the earth's field should pass through the square at right angles to the plane of magnetization.

Tests were made with both continuous and alternating current. For the continuous-current tests a ballistic galvanometer having a 12-second period was employed, the magnetizing current being reversed by a switch in the usual manner. A 2-way switch was introduced into the secondary circuit so that the galvanometer could be isolated from the windings whilst being short-circuited on itself. The secondary windings were thus never short-circuited, and the introduction of artificial viscosity was avoided.

The alternating-current tests were made with an ammeter in the primary circuit to measure H , and B was measured with a combination of rectifier and calibrated galvanometer taking current from the secondary circuit. An adjustable mutual inductance was also included for the purpose of measuring the phase angle and the losses.

* The field has to a certain extent been explored by Wilson, Gumlich, Kummer, and Fromme (see Bibliography, p. 105).

The arrangement of circuits for carrying out the alternating-current tests is shown in Fig. 2. I represents the magnetic square, wound with primary P and secondary SW. In series with P there is the primary winding of the adjustable mutual inductance M, the ammeter A, and adjustable resistance R. C represents a rectifying commutator run by a synchronous motor. One pair of brushes

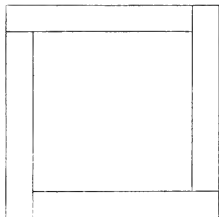

FIG. 1.

from this is connected to the galvanometer G through an adjustable resistance. G can be calibrated in volts and its constant varied by altering the resistance in series with it. It is in fact a voltmeter having a very large number of ranges and taking only a very small current. S is a 3-way switch connected so as to short-circuit the rectifier on itself, secondly to include the secondary winding of the

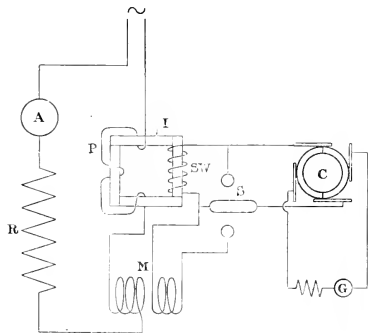

FIG. 2.

magnetic square, and thirdly to include also the secondary of the mutual inductance, the E.M.F. from which should be very nearly in opposition to the E.M.F. in the secondary of the magnetic square.

Neglecting for the moment the effect of thermal E.M.F.'s, the method adopted was as follows:—

S was placed on the middle stud, the rectifier brushes were rocked until the position which gave the maximum

reading on G, and the primary current was then adjusted until the desired reading was obtained on G.

Assuming that the primary current is a perfect sine wave, H_{max} can be calculated from the formula—

$$H = \frac{0.4 \pi T I}{l} \sqrt{2},$$

where T is the number of ampere-turns and l is the length of the magnetic circuit in centimetres. B_{max} may be calculated from the formula—

$$B_{max} = \frac{V \times r_0}{4 f A T},$$

where V is the rectified voltage, f is the periodicity, A is the area of the iron, and T is the number of secondary turns.

Having obtained these readings, S was next placed on the bottom stud and M was adjusted until G read zero. S was then returned to the middle contact and the rectifier brushes were rocked round until G again read zero. S was

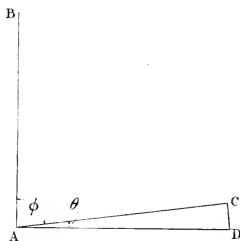

FIG. 3.

then put again on the bottom contact and the galvanometer reading was taken.

This last reading divided by the first equals $\cos \phi$. This again multiplied by the number of primary ampere-turns gives the loss in terms of ampere-turns. This again multiplied by the rectified volts per turn and the form factor gives the loss in watts.

In rectifying very small voltages the author has found it necessary to employ a very considerable pressure between the brushes and the commutator. The whole rectifier consequently gets very hot and thermal electromotive forces are developed. It was therefore found necessary to work to a false zero when taking the lower readings. This was obtained by turning the switch on to the top contact, when the rectifier was short-circuited upon itself. This had to be done at each stage as the thermal E.M.F. was continually changing.

Referring now to Fig. 3, let AB represent the current in amperes, AC the voltage in the secondary of the magnetic square, and AD the voltage in the secondary of the mutual inductance. Then CD divided by AC equals $\tan \theta$; if θ is small this is practically equal to $\sin \theta$. Now $\sin \theta$ equals $\cos \phi$; therefore CD divided by AC equals $\cos \phi$.

Another way of representing the idea is as follows:—

The secondary voltage from the magnetic square may provisionally be considered to be a sine wave, and is commutated at zero. The mutual-inductance secondary voltage is a sine wave nearly in opposition to the first wave, and may be resolved into two components, one equal to and in phase with the first wave, and a second component of small magnitude in quadrature. When the brushes are shifted through 90 degrees, the quadrature component commutates at zero and is the only one to cause a unidirectional current to flow through the galvanometer.

So far sine waves have been assumed throughout. The case is, however, a little more complicated.

The alternator employed gives an almost perfect sine wave of electromotive force at small loads. The reactive voltage of the magnetic square was too small to affect the current wave. The calculation of H_{max} may therefore be taken as correct so far as wave form affects it. The formula for calculating B_{max} is independent of wave form. With a sine current-wave the mutual-inductance electromotive force will also be a true sine, although any very small harmonic in the current will be exaggerated in the E.M.F. wave.

At very low inductions, when the permeability assumes a constant value, the secondary voltage of the magnetic square should be nearly a sine wave. At the higher inductions, however, B not varying proportionally with H , the flux wave should be peaked and the E.M.F. wave should be flat-topped.

With the secondary of the magnetic square connected approximately in opposition to the secondary of the mutual inductance, we have the following:—

- The fundamental wave produced in the transformer winding.
- Harmonics in phase with A, also produced in the transformer winding.
- A component from the mutual inductance, exactly neutralizing A.
- A component from the mutual inductance in quadrature with A.
- Harmonics produced in the transformer in quadrature with A.

With the switch on the middle contact the galvanometer measures the algebraic mean of $A + B$ through a half period, that is, the mean ordinate of the fundamental + $\frac{1}{2}$ of the third harmonic, $\frac{1}{2}$ of the fifth harmonic, etc.

With the switch on the bottom contact and the brushes of the rectifier shifted through 90 degrees, the galvanometer measures the algebraic mean through a half period of $D + E$, that is, the mean ordinate of $D + \frac{1}{2}$ of the third harmonic, $\frac{1}{2}$ of the fifth harmonic, etc.

A wattmeter would have taken account of D only, consequently the power-factor reading obtained is in error by an amount depending upon the magnitude of E.

By rocking round the brushes in small regular steps when the switch was on the middle contact the ordinates of the flux wave could be obtained. This was done for $B_{max} = 100$ in the case of Stalloy and Lohys. No trace of quadrature harmonics could be detected, indicating that the method

* By the term "in phase" when applied to harmonics is meant that they are zero when the fundamental is zero and their direction is such as to raise the mean ordinate of the resultant wave.

of test should give the same results as would have been obtained by a wattmeter. Further, a wattmeter test was actually carried out on Stalloy at $B_{max} = 100$ at 50 periods, and the result was in agreement within 1 per cent of the result obtained by the rectifier method.

From the flux wave plotted for $B_{max} = 100$ the form factor of the E.M.F. wave was calculated and came to 1.00 for both samples, showing the wave to be flat-topped, as already stated. A small error is introduced by employing a galvanometer consuming power. At $B_{max} = 1$ the power consumed was about 2 per cent of the measured loss in the iron. At higher flux densities the galvanometer took considerably less than this proportion.

The general data concerning the samples will be found in Table A.

TABLE A.

H (continuous current) = ampere-turns $\times 0.0182$		
H (alternating current) = ampere-turns $\times 0.0182 \times \sqrt{2}$		

THE AFTER-EFFECT OF DEMAGNETIZATION.

The specimens were demagnetized as follows: The squares were magnetized up to about $B_{max} = 10,000$ at 50 periods, and the alternator field-current was gradually reduced to zero, leaving the iron, however, still subjected to a small magnetizing force, due to the residual magnetism of the alternator. The alternator was then shut down, the circuit not being interfered with until the machine had quite stopped rotating.

As soon as the alternator had stopped, the connections were made for carrying out the ballistic tests. The magnetizing current was reversed 20 times at 2-second intervals with the galvanometer isolated from the secondary. The galvanometer was then coupled to the secondary, and, 2 minutes after the alternator had stopped, the magnetizing current was reversed and the throw of the galvanometer taken. A second throw in the reverse direction was taken at 4 minutes. The average of these two was considered to be the throw at 3 minutes.

A second pair of throws were taken at 6 and 8 minutes and were averaged to obtain the throw for 7 minutes. Throws were taken after this at suitable intervals up to 72 hours. The current was reversed 20 times at 2-second intervals before each throw was taken.

The results of these tests are given in Tables B and C. Referring to Table B, it will be observed that what may be called the ballistic permeability of Lohys falls quickly

at first and afterwards more slowly up to about 48 hours. The total fall is 5.2 per cent from $B = 286$, 40 per cent from $B = 161$, and 1.8 per cent from $B = 121$. From this, one might say that the fall is greatest at very low inductions and continually decreases as the induction is increased.

TABLE B.—LOHYS.

Showing the decrease of permeability with time after demagnetization. Magnetizing force constant throughout each experiment.

Time in hours	B	μ	B	μ	B	μ
0.05	286	310	161	372	121	619
0.133	285	309	160	370	121	619
0.25	284	308	159	369	120.5	616
0.67	283	306	159	369	120.5	616
2	282	305	158.5	367	—	—
3	281	304	158	366	—	—
5	279	302	—	—	—	—
24	274	296	155	360	119.5	611
48	272	294	154	357	119	608
72	272	294	154	357	119	608
Total fall	5.2 %		40 %		1.8 %	

Referring now to Table C it will be observed that the fall of ballistic permeability is very much greater for Stalloy than for Lohys. The fall, moreover, takes longer to arrive at completion. The total fall observed was 20 per cent from $B = 288$, 25 per cent from $B = 206$, and 7 per cent from $B = 127$. As before there is a decrease of the fall as the induction increases, but there is also a decrease of the fall in the other direction.

TABLE C.—STALLOY.

Showing the decrease of permeability with time after demagnetization. Magnetizing force constant throughout each experiment.

Time in hours	B	μ	B	μ	B	μ
0.05	288	500	206	693	127	1,030

72	230	400	155	520	118	960
Total fall	20 %		25 %		7 %	

It was found that after the permeability had fallen it could again be partially restored by subjecting the iron to a sharp blow or a series of blows. For example, the Stalloy square was magnetized with a force of $H = 0.0298$; 48 hours after demagnetization the value of B obtained was 156. The square was then dropped 6 times on to the floor through a distance of 6 in., the magnetizing current

being switched off for the time being. After 20 reversals at 2-second intervals the value of B was found to be 188. The iron was then demagnetized, and 3 minutes later the value of B was found to be 206. In this case a series of blows produced 64 per cent of the effect of demagnetization treatment.

On alternating current Stalloy behaves in much the same way. At $B_{max} = 1$ the permeability one hour after the demagnetization treatment was found to be 392. At 48 hours it had declined to 360.

VISCOSITY.

The ballistic galvanometer employed had a period of 12 seconds. It thus arrived at the end of its swing in 3 seconds, and any impulse received after this period was not recorded in the throw.

The loss of throw due to the delayed impulse was approximately determined in the following manner. The magnetizing current was reversed and the throw taken in the ordinary way. Next the current was reversed with the galvanometer isolated; and 3 seconds later the galvanometer was switched in and the delayed impulse recorded. Further tests were made after 6, 9, 12, and 15 seconds. All these additional throws were added together and taken as the total loss of throw due to the delayed impulse.

The results of these tests are given in Table D. On the whole the viscosity is greater for Lohys than for Stalloy. At $B = 15$, however, Stalloy shows the larger viscosity. The viscosity loss falls off greatly at $B = 120$.

TABLE D.

Showing the estimated reduction of throw of the galvanometer spot on account of viscosity.

B	Lohys	Stalloy
27	6.0 %	3.5 %
15	3.0 %	3.7 %
120	1.0 %	0.5 %

Taking each sample separately the variation of viscosity loss is of the same order as the variation of permeability fall some time after demagnetization. It rather looks as if there might be some connection here.

The above tests were made one hour after demagnetization treatment and again after 48 hours. Although the permeability meanwhile had declined there was no difference observed in the viscosity loss.

Another peculiar effect of viscosity is that it has a greater influence upon the ballistic throws when the reversal of the magnetizing current is divided into two parts, that is, the current is broken and the throw taken and then the current is re-made in the reverse direction and the throw taken.

This is shown in Tables E and F.

Referring to Table E it will be observed that Lohys shows a difference of 1.6 per cent at $B = 28$, 3.9 per cent at $B = 159$, and 1.4 per cent at $B = 120$. It is worthy of remark that whilst the viscosity loss on reversal was

found to be greatest at $B = 2.8$, the difference between the throws on reversal and "break and make" was greatest at $B = 15.9$.

TABLE E.—LOHYS.

Showing the difference between the throws on first breaking the magnetizing current and then remaking it in the reverse direction, as against reversing in one operation.

B	Galvanometer Throws				
	Break	Make	Break + Make	Reverse	Difference
2.8	160.5	61.5	121.5	123.5	1.6 %
15.9	179	93	172	179	3.9 %
129	103	170	273	277	1.4 %

Referring now to Table F it may be noted that a difference as high as 8.4 per cent was actually found at $B = 20$ for Stalloy. At $B = 2.3$ the difference was only 0.5 per cent, and at $B = 118$ it was only 0.4 per cent. The

TABLE F.—STALLOY.

Showing the difference between the throws on first breaking the magnetizing current and then remaking it in the reverse direction, as against reversing in one operation.

B					
	Break	Make	Break + Make	Reverse	Difference
2.3	49.5	50	99.5	100	0.5 %
6.8	141.5	145	286.5	292	1.9 %
13	128	135	263	272	3.3 %
20	88.5	108.5	197	215	8.4 %
118	114.5	149.5	264	265	0.4 %

explanation of these figures is far from obvious. Previous experimenters have attempted to measure ballistically the hysteresis loss in iron. In view of these figures now tabulated it would appear that such attempts are bound to be rather abortive when measurements below $B = 100$ are essayed.

Another peculiar effect of viscosity is that it may to a certain extent be reduced by carrying out reversals at rather long intervals. The Stalloy square was subjected to a constant magnetizing force which was reversed 22 times at 2-minute intervals. The results of these tests are given in Table G.

The value of B recorded was 15.4 for the first pair of reversals. This subsequently increased quickly at first and more slowly afterwards to 16.1 for the 17th and 18th reversals, after which no further increase could be found. The tests were repeated with the specimen subjected to 20 reversals at 2-second intervals between each 2-minute interval and exactly the same throws were obtained. Evidently each successive reversal at 2-minute intervals

widens the limit of magnetization, but 2-second reversals never allow the iron to attain to even the previous limit.

TABLE G.—STALLOY.

Showing the effect of carrying out repeated reversals at intervals of 2 minutes. Test carried out 48 hours after demagnetization.

Average of Reversals		B
1 and 2	3 and 4	
3	4	15.4
5	6	15.6
7	8	15.75
9	10	15.85
11	12	15.9
13	14	15.95
15	16	16.0
17	18	16.05
19	20	16.1
21	22	16.1

Total rise: 4 per cent.

It appears probable that if the squares could be first subjected to demagnetization treatment and then to a magnetizing force maintained constant for several days, the value of B actually attained at the end of this time would be materially higher than would be indicated by any ballistic tests made by reversing the magnetizing current.

Probably the only way actually to measure the true continuous-current permeability would be to break the magnetic square and withdraw the ballistic coil. The author has not found this method practicable.

FLUX DENSITY AND PERMEABILITY.

Ballistic tests were made 48 hours after the demagnetization treatment and the results are given in Tables H and I.

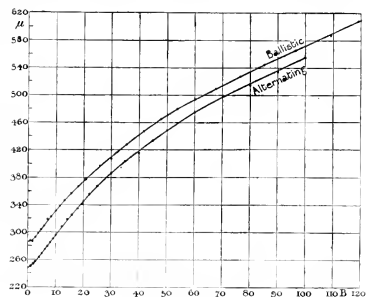

FIG. 4.—LOHYS.

The tests were commenced at the lowest induction and carried upwards, the magnetizing current being reversed 20 times at 2-second intervals after each adjustment.

Alternating-current tests of permeability were also made 48 hours after the demagnetization treatment and the results obtained are given in Tables J, K, L, and M. The permeability was found to be the same for 25 and 50

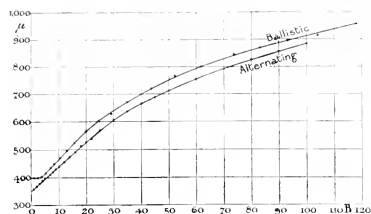

FIG. 5.—STALLOY.

periods, such small differences as were actually measured being within the range of possible experimental error.

The ballistic and alternating permeabilities have been plotted as curves in Figs. 4 and 5. Referring to Fig. 4

TABLE H.—LOHYS.

Showing the permeability obtained 48 hours after demagnetization, the magnetizing force being reversed 20 times at 2-second intervals before each test.

0'196	119'0	608

it will be seen that the permeability of Lohys is considerably less on alternating current, the difference decreasing as the induction increases. Stalloy on the other hand shows a great peculiarity at very low inductions. At $B = 3$ the ballistic permeability attains a constant

value, but the alternating permeability continues to fall as far as $B = 1$ and possibly right to zero.

The permeabilities are further compared in Tables P and Q. With Lohys the difference is 1'43 per cent at $B = 0$, continually decreasing to 3'0 per cent at $B = 100$. With Stalloy the difference is 12'5 per cent at $B = 0$, 4'8 per cent at $B = 5$, 0'2 per cent at $B = 20$, and then continually decreases till it gets down to 2'7 per cent at $B = 100$.

There is every indication that the difference between ballistic and alternating permeability would become little or nothing at higher inductions.

From these tests it would appear that the permeability of iron can be divided into two parts, the one independent

TABLE I.—STALLOY.

of frequency, the other only becoming apparent when the frequency is extremely low. The case is somewhat analogous to the absorption of a condenser. At $B = 1,000$ and upwards the absorption flux may be said to be very small by comparison with the whole flux, but between $B = 1$ and $B = 100$ the absorption flux forms quite a large proportion of the whole.

ENERGY LOSSES.

Tables J, K, L, and M besides giving the permeability also give details of the magnetizing current, power factor, and losses at 25 and 50 periods. The eddy-current loss was determined at $B_{max} = 10,000$ and 25 and 50 periods by a wattmeter test. It has been assumed that the eddy loss in ampere-turns may be taken as proportional to B_{max} .

An error is no doubt introduced in the estimation of the eddy-current loss by reason of the E.M.F. wave being slightly flat-topped; the amount of this error is not quite known, but it should not exceed 2 per cent, the difference

between the form factor of a sine wave and the wave form found at $B_{\max} = 100$.

The hysteresis losses have been plotted as curves in Figs. 6 and 7. The upper curve in each case covers the

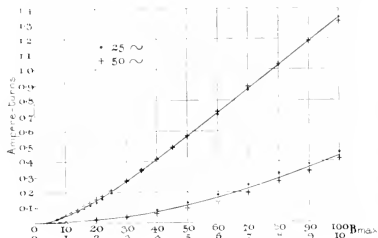

FIG. 6.—LOHYS.

whole region up to $B_{\max} = 100$, and the lower curve from $B_{\max} = 0$ to $B_{\max} = 10$. The dots represent readings at 25 periods and the crosses at the 50 periods.

Watts per lb. = $B_{\max} \times$ in-phase ampere-turns $\times 0.00000192$.

There is a considerable difference at some points between the results recorded at the two periodicities. These differences are too persistent to be ascribed to

errors of reading or adjustment. Either the differences are real or else between the two tests there must have been some difference of conditions. Very likely there

are conditions affecting the magnetization of iron at low densities that have not yet been suspected. One thing is clear that the differences arise from a difference of power factor rather than a difference of magnetizing current.

The losses are given in ampere-turns rather than watts, as this make clear curves possible over a long range. To obtain the results in watts, the ampere-turns require to be multiplied by the volts per turn. The conversion constants are given at the foot of the tables.

If hysteresis watts varied as the square of B_{\max} , the ampere turns would vary proportionally to B_{\max} , and the curves would be simple straight lines passing through

Watts per lb. = $B_{\max} \times$ in-phase ampere-turns $\times 0.00000105$.

It was particularly desired that the retentiveness should be measured with the highest degree of accuracy obtainable. It was necessary, therefore, to arrange that all throws

the origin. A lower hysteresis index than 2 would require the curves to be convex, instead of which they are about straight from $B_{\max} = 100$ down to $B_{\max} = 30$, and then become concave, indicating that the hysteresis index is over 2 throughout. The hysteresis indices up to $B_{\max} = 10$ have been calculated and are embodied in Tables N and O. The index is in the neighbourhood of 3 for both samples at the lower flux densities. Whether it attains any higher value below $B_{\max} = 1$ has not been established.

It was considered desirable to make a comparison between ballistic and alternating-current methods of measuring hysteresis, although there was no expectation of any agreement being obtained.

If the two sides of a hysteresis loop are parallel, all the ordinates are equal, and it should only be necessary to

should be as large as possible. With the coils employed for the previous tests a throw to the full length of the scale could not be obtained with a value of B_{\max} less than about 75. The accuracy desired could not therefore be obtained

at lower values. The tests were made, therefore, on a high-tension transformer having a core of Stalloy. It was found that single throws varied as much as 0.5 per cent either side of the mean. By taking from 30 to 50 throws, however, the author reckons to have obtained an accuracy to 0.1 per cent, or better.

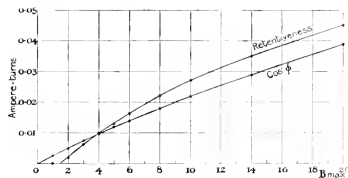

FIG. 8.—STALLOY.

The power factor was afterwards measured on the same transformer, and after allowing for eddy currents the power factor due to hysteresis alone was determined. The power factor due to hysteresis only and retentiveness are compared in Table R and Fig. 8. It will be noticed that

TABLE P.—LOHYS.

Showing the difference between the ballistic and alternating permeability taken 48 hours after demagnetization.

B_{max}	Permeability		Difference	Per cent
	Ballistic	Alternating		
0	286	245	41	14.3
5	306	270	36	11.8
10	332	290	36	10.8
20	375	345	30	8.0
30	410	385	25	6.1
50	470	450	20	4.3
75	525	507	18	3.4
100	572	555	17	3.0

the curves cross at $B_{max} = 4$, and whilst $\cos \phi$ appears to reach zero at $B_{max} = 0$, the retentiveness reaches its zero value at $B_{max} = 1.5$. It is certain that at $B_{max} = 1$ no retentiveness whatever could be detected. It is also certain

that on alternating current no amount of adjustment or allowance for possible errors could cause $\cos \phi$ to come out lower than 0.002 at $B_{max} = 1$.

The conclusion appears to be that the hysteresis loss per cycle is not independent of the frequency at these very low inductions.

TABLE Q.—STALLOY.

Showing the difference between the ballistic and alternating permeability taken 48 hours after demagnetization.

B_{max}	Permeability		Difference	Per cent
	Ballistic	Alternating		
0	400	350	50	12.5
5	415	395	20	4.8
10	405	440	25	5.7
20	505	530	35	6.2
30	640	605	35	5.5
50	750	715	35	4.7
75	850	815	35	4.1
100	910	885	25	2.7

There is one discrepancy which ought in fairness to be mentioned. Some two years ago, when the author knew but little of the necessity of keeping to standard conditions, this same transformer was tested for retentiveness and it

TABLE R.—STALLOY.

Showing the comparison between ballistic retentiveness and the power factor after deducting eddy currents.

B_{max}	$\cos \phi$	Retentiveness
1	0.0025	Nil
2	0.005	0.002
3	0.007	0.006
4	0.0095	0.010
5	0.012	0.013
6	0.014	0.016
8	0.018	0.022

14	0.030	0.035
20	0.039	0.045
100	0.105	0.125

was then found that the retentiveness curve reached zero at $B_{max} = 3.5$. What the special conditions were that brought this result about, the author has tried and failed to ascertain.

It should be mentioned that all the tests referred to in this paper were carried out at a practically constant room temperature, namely between 64° and 66° Fahr.

CONCLUSIONS.

Subjecting the iron to demagnetizing treatment has a sort of loosening effect upon the molecular magnets, so that directly afterwards reversing the magnetizing force leads to an abnormal change of flux and an abnormally high permeability.

A series of sharp blows given to the iron whilst not subjected to a magnetizing force has a similar effect to the above.

In both cases the effect wears off with time, 48 hours being about the time required to reach normal conditions.

At flux densities between $B = 1$ and $B = 100$ the process of magnetization is so slow that no ordinary ballistic galvanometer can include the whole change of flux on reversal of the magnetizing force.

When the reversal of magnetizing force is divided into two parts, the change of flux takes place even still more slowly than on a simple reversal, so that attempts to measure the hysteresis loss ballistically are likely to be very misleading.

Permeability on alternating current is sensibly the same at 50 as at 25 periods. Ballistic permeability is higher and true continuous-current permeability the highest of all.

The hysteretic index is in the neighbourhood of 3 on alternating current between $B_{\text{rev}} = 1$ and $B_{\text{max}} = 10$. Above $B_{\text{max}} = 10$ the index continually declines, but it is still above 2 at $B_{\text{max}} = 100$.

On alternating current hysteresis loss is present right down to $B_{\text{max}} = 0$, notwithstanding the fact that no retentiveness could be detected below $B_{\text{max}} = 1$ on ballistic tests.

DYNAMOS FOR MOTOR ROAD-VEHICLE LIGHTING.

(SECOND PAPER,)*

By J. D. MORGAN, Associate.

(Paper received 20th October, 1913.)

In a former paper † the author described a number of representative generators for use in the electric lighting of motor road-vehicles. The present paper is intended to be supplementary to the former one, and gives an account of the more important more representative machines of a number which the author has recently had occasion to test.

The question of efficiency has not yet become of serious importance in car-lighting dynamos, as the power required by them is comparatively small, and the necessity for good regulation over a large range of speed variation is greater than the demand for economical generation. There is, however, at present a movement in the direction of making the dynamo convertible, so that it can also be used as a motor for engine-starting purposes. In this connection it is necessary to give attention to efficiency if the machine is

b. The machine is adapted for operation with an 8-volt battery of about 75 ampere-hours' capacity. At low speeds all the windings contribute to the excitation of the machine, but as the speed increases the current flowing through *c* diminishes, and the excitation is correspondingly diminished. Above a certain speed the current through *c* reverses in direction and increases with further increase of speed. Simultaneously the current in *a* diminishes until it finally reaches zero value, the return to the machine being then entirely through the winding *c*. The excitation therefore progressively diminishes with increase of speed, and the action of the windings *a* and *c* enables an extraordinary amount of field variation to be obtained. With

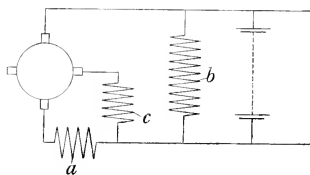

FIG. 1.

required to run without modification as a motor. Efficiency tests have therefore been made on the machines described. Such tests are based upon measurements of the net tension of the driving belt.

MACHINES WITH COMPENSATING WINDINGS.

It is well known that if in conjunction with a pair of ordinary brushes placed centrally between a pair of poles there is employed an extra brush placed mid-way between the two ordinary brushes and connected to one of these through a field winding, the current through the said winding reverses its direction after a certain speed has been exceeded. This fact is utilized in an ingenious manner by Messrs. Joseph Lucas, Ltd.

Fig. 1 illustrates the arrangement of the windings in a machine recently produced by them. Three distinct windings are adopted, *a* being a series winding connected to the negative brush, *b* a shunt winding connected to the positive brush and the end of *a* remote from the negative brush, and *c* a shunt winding connected between the intermediate brush and the junction of the windings *a* and

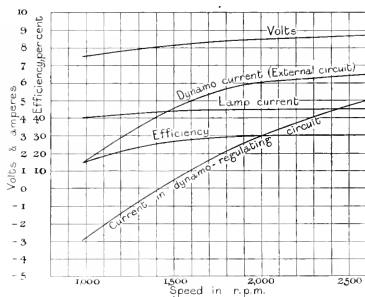

FIG. 2.

this arrangement the regulation is very good, as is shown by Fig. 2. The voltage and current increase to a maximum and then remain practically constant, notwithstanding a large increase in the speed of rotation. In the figure only the earlier portion of the test is recorded, as it is the behaviour at the lower speeds which enables an opinion to be formed of the merits of these machines, provided, of course, that at the higher speeds there is no serious variation of voltage or current; for in addition to the necessity for constancy of the maximum voltage it is important that the maximum should be reached quickly, and when the voltage rise is slow the range of speed over which the machine is useful is limited.

It will be observed that the maximum output of the machine is only about 2 amperes higher than that required by the lamps. The necessity for this was indicated by the author in the earlier paper, and it is interesting to note that manufacturers are generally

* *Journal I.E.E.*, vol. 48, p. 749, 1912.† *Loc. cit.*

realizing the fact that a current output largely in excess of the requirements is detrimental both to the battery and the regulation. When it is impossible to avoid a relatively excessive output at high speeds means are sometimes adopted for cutting out the dynamo from the system after the current has exceeded a predetermined value.

The efficiency of the Lucas machine, as in all electrically regulated machines, is low, being only 30 per cent at

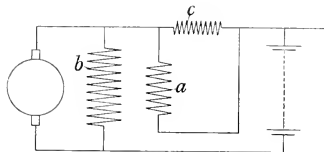

FIG. 3.

the highest. But this figure remains remarkably constant after it has been attained, a result due no doubt to the fact that the winding *a* goes out of action at the higher speeds.

In the same class as the above is the machine of Messrs. Rushmore, Ltd. This is illustrated in Fig. 3. A demagnetizing winding *a* is employed in conjunction with

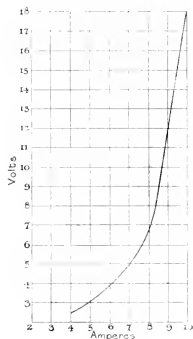

FIG. 4.

an ordinary shunt winding *b*. The winding *a* is arranged in shunt with an iron-wire resistance *c*. Regulation of the demagnetizing current through *a* is obtained by taking advantage of the known peculiarity in the variation of the temperature coefficient of resistance of iron. When a small current passes through *c* the potential drop in the coil is small, and in consequence the winding *a* has little effect upon the operation of the machine. But as the current through *c* increases, the potential difference across

the ends of the coil increases largely, and in consequence a rapidly increasing current is diverted through the winding *a*. This result, though depending upon a perfectly well-known property of iron, finds an interesting application in the Rushmore machine, and a curve is therefore shown in Fig. 4 to illustrate the variation of potential and current in an iron-wire coil. From this it is evident that small variations in the higher values of the current passed through the coil would cause relatively large variations in the current through a winding connected to the ends of the coil.

The machine tested was adapted to operate with a 6-volt

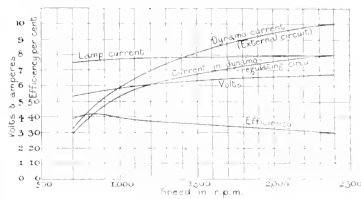

FIG. 5.

battery, and in the tests a battery of about 75 ampere-hours' capacity was used. A typical result of a large number of tests is shown in Fig. 5. It will be seen that the regulation is good, and the efficiency, though low, is of the same order as is usually found in this class of machine. Compared with the Lucas machine, the efficiency curve possesses a different characteristic in that it gradually falls from the maximum with an increase of speed.

MACHINES UTILIZING ARMATURE REACTION.

Of this class the machine made by Messrs. Broth, Ltd., is a good example. In its simplest form (which is illus-

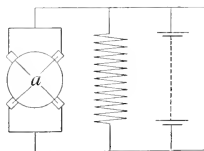

FIG. 6.

trated by the diagram in Fig. 6) it consists of an ordinary shunt-wound dynamo fitted either with exceptionally broad brushes or with an equivalent pair (*a*), each of which consists of two electrically connected parts arranged so as to subtend a large arc on the commutator and to short-circuit a number of coils on each side of the armature. According to the makers, the object aimed at is to short-circuit those armature conductors which are intersecting the cross-field produced by the conductors under the main pole-pieces, and by the currents thus obtained to create a

regulating flux which directly opposes the main flux. Auxiliary poles (wound or unwound) may be arranged adjacent to the short-circuited conductors to intensify the cross flux. In the machine tested there were no auxiliary poles and the brushes were of the divided type as illustrated.

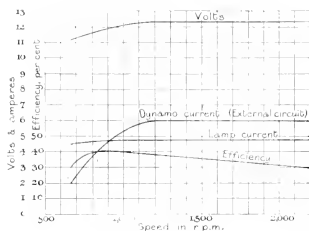

FIG. 7.

The machine was designed to work at 12 volts and was tested in conjunction with a battery of 75 ampere-hours' capacity. Fig. 7 gives curves which are representative of

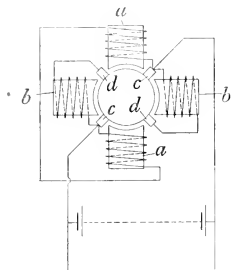

FIG. 8.

the normal working of the machine. The high quality of the results is self-evident, the maximum voltage being quickly reached, and both the voltage and the current being kept constant over a wide range of speed variation. The efficiency curve has a somewhat similar characteristic to that of the Rushmore machine, and is similar to the curves usually obtained in electrically regulated machines.

Another machine which depends upon armature reaction for its self-regulating property is that made by Messrs. C. A. Vandervell & Co. One of the most recent forms of their machine is illustrated in Fig. 8. It consists of a pair of main pole-pieces *a* and a pair of auxiliary pole-pieces *b*. The former are provided with an ordinary shunt winding, and each of the latter is fitted with a winding which is connected between one of the main brushes *c* and an auxiliary brush *d*. The action of the machine in detail is somewhat complicated. But in the main the action appears to be as follows:—At low speeds the conductors between the brushes *c* and *d* cutting the residual magnetism of the pole-pieces *b* produce a current in the windings on *b*, the flux due to which opposes the said residual magnetism. When the speed increases beyond that at

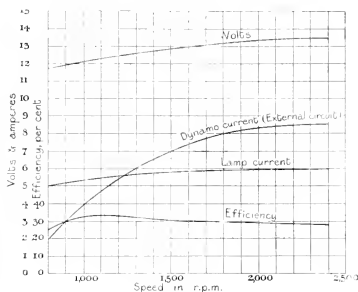

FIG. 9.

which the residual magnetism of the poles *b* is neutralized, the direction of the current through the conductors between *c* and *d* and the windings on *b* reverses, whereupon a field is produced which acts in opposition to the field of the pole-pieces *a*. This opposition increases with the speed and produces the required regulation at the higher speeds. A typical result of tests on this machine is shown in Fig. 9, from which it will be seen that the regulation is good.

At the present time the electrically regulated machines appear to be more in favour than those which are regulated by a slipping clutch. The mechanical simplification obtained in the electrically regulated machines is not, however, an unmixed blessing, as special precautions have to be taken to avoid injurious effects from over-heating.

* A full account is given in the British Patent Specification No. 17838 of 1912.

I. INTRODUCTORY.

One of the author's objects in presenting this paper is to dispel an idea, which he believes generally exists outside the Post Office, that engineering work in the Post Office is practically confined to telegraphy and telephony. As a matter of fact the various applications of power cover a considerable proportion of the whole field of power engineering, including the generation and conversion of electric power, pneumatics, hydraulics, heating, ventilation, transportation, and lighting, as well as those applications directly connected with telegraph and telephone circuits.

It is hoped that the following particulars of the problems which present themselves and the manner of their solution will be of interest to members, and that their publication may also serve as an inducement to engineering contractors to interest themselves in designing plant to meet the required conditions. It will only be possible within the limits of a single paper to indicate briefly what is being done and attempted, and the author must also request the indulgence of members as regards the absence of much information which, for official reasons, he is unable to give.

II. GENERATION AND CONVERSION OF POWER.

Until recently the energy for power and lighting in London and seven of the larger provincial towns has been supplied from small power houses situated in the basements of the Post Office buildings, and some of these stations have been in existence for about 20 years. In the Metropolitan area two of these old power houses have recently been replaced by the new electric power system which has been laid down to meet the growing demand for power, and to generate under more economical conditions.

The new system at present includes a main generating station and three sub-stations, the generating station being situated on the south side of the river, near Blackfriars Bridge, and the three sub-stations being in basements at King Edward Building, G.P.O. West, and Carter-lane.

Fig. 1 is a key diagram of the power supply. Electric power is generated as three-phase alternating current with a frequency of 50 periods per second, and at a pressure of 6,600 volts, and transmitted at this pressure to the three sub-stations.

At G.P.O. South (Carter-lane) the three-phase supply is transformed down to 110 volts for the supply of the lighting circuits.

At King Edward Building the three-phase supply is transformed down to 440 volts for power and to 110 volts for lighting.

At G.P.O. West sub-station the three-phase supply is converted by motor converters to continuous current at 220 volts, the power circuits being supplied from the outers and the lighting circuits from either side of a 3-wire system worked in conjunction with a storage battery.

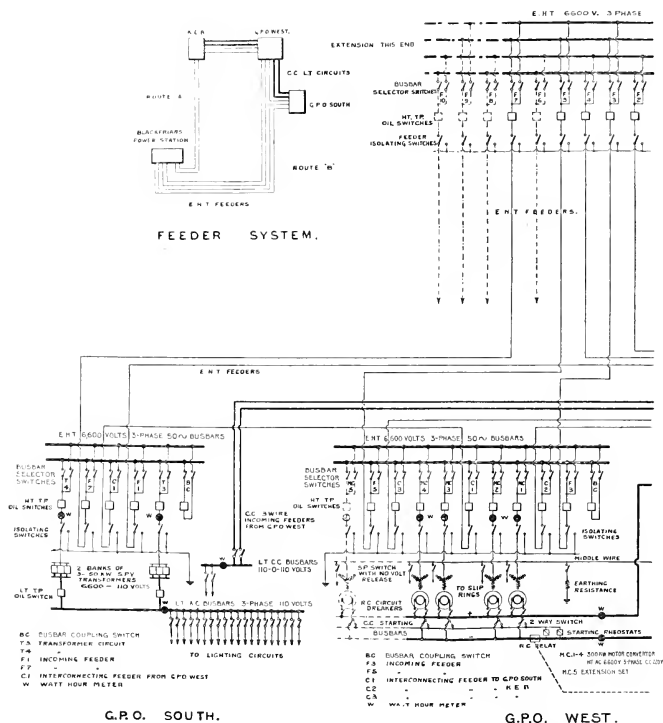

By means of suitable relays at the sub-station end of the extra-high-tension feeders and in the continuous-current busbars it has been arranged that in the event of temporary interruption to the e.h.t. supply from the power house the battery will for a considerable time not only maintain the supply to the continuous-current circuits but will also by running the motor converters reversed as e.h.t.

generators automatically maintain the pressure on the e.h.t. bus-bars at the other two sub-stations, and so enable the transformers to maintain the alternating-current supply.

The normal full load capacity of the main generating plant, including spares at the power house, is 2,500 kw., and

Table A (see p. 112), giving an extract from the weekly analyses of operation, and Fig. 2, which illustrates a representative load curve, will probably be of interest. Although the present total output is so small the extremely favourable character of the load curve has enabled us to

BLACKFRIARS

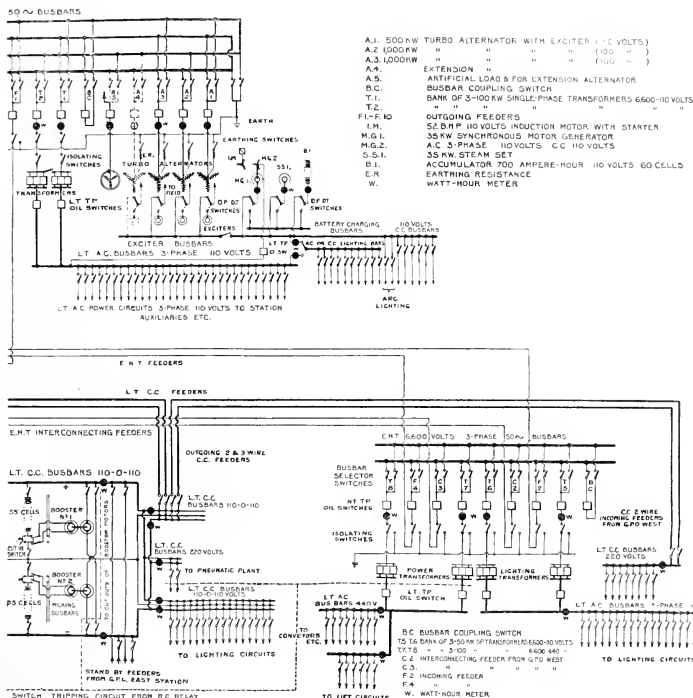

growing demands in the space available, and to the favourable arrangements which it has latterly been possible to make with certain local authorities.

Owing to the fact that the exhaust steam supplemented by a certain amount of live steam has been used for heat-

In some cases the favourable load curve has enabled a sufficiently low price to be obtained for a direct supply at the standard low pressures for power and lighting without special arrangements, this result being facilitated by the recent improvements in metal filament lamps and their

POWER STATION

SUBSTATIONS.

G.P.O. Electric Power Supply.

ing purposes it has not been so easy to justify the shutting down of these non-condensing stations on purely financial grounds as might be imagined. In each case, the existing cost of supplying all services has had to be carefully compared with the cost of the purchased electrical units, plus the cost of additional heating and steam cooking plant, taking into consideration of course the capital charges involved in each case.

K. E. B.

employment in groups of high-candle-power units for general lighting. In other cases the required price per unit has been obtained by installing a battery to enable the value of the local factor to be increased, the advantage also being obtained of a stand-by for emergency purposes.

At Birmingham an e.h.t. bulk supply is taken from the Corporation in the form of three-phase current at 25 periodicity and 5,000 volts pressure, and is transformed

and converted by rotary converters to continuous current of 220 volts, the power circuits being supplied from the outers and the lighting circuits from the inners of a 3-wire system worked in conjunction with a battery. The Birmingham sub-station contains two 150-kw. rotary converters and two 10-kw. boosters, the battery which has a capacity of 750 ampere-hours at the 3-hour rate being placed in a room overhead. The sub-station also accommodates two pneumatic pumping sets, each driven by a 34-kw. motor.

The lifts in the building which have been worked by hydraulic power will ultimately be replaced by electric

lifts, the service being maintained in the meantime by temporary electrically-driven hydraulic pumps.

III. PNEUMATICS.

Pneumatic tubes have been used in London since 1871, and in Dublin, Glasgow, Liverpool, Manchester, Birmingham, Newcastle and other places prior to 1866, while since the latter date their use has been extended in some form or another to practically every telegraph office of appreciable size in the kingdom, the total capacity of the power-driven pumping plant installed for this purpose being about 2,200 h.p. In the earlier installations the pumps were driven by steam engines or gas engines, but it is now the practice to employ electrically-driven pumps. The original four 120-h.p. engine sets at G.P.O. West have

recently been replaced by four electrically-driven 240-h.p. sets each having a free air capacity of 3,600 cubic ft. of air per minute, which are operated from the new electric power system.

For smaller installations, where space is not quite so important as at the G.P.O., low-speed sets belt-driven from electric motors are usually employed, and, generally speaking, lend themselves to the most efficient and economical working. Water-cooled cylinders are employed in all cases, and air containers, both pressure and vacuum, are provided as required. Several systems of automatic regulation are in use, electrically operated valves of our own design used in conjunction with pressure gauges fitted with contacts and relays having given the most satisfactory results. A system of "pumping through" by which the air drawn from the vacuum mains is compressed and used for the pressure service, has been adopted with advantage in some cases and is in use at the General Post Office; it results in a saving in the space required and in a slightly

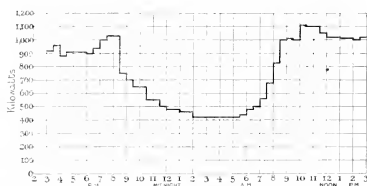

FIG. 2.—Daily Load Curve (25th April, 1913) of G.P.O. Power Station at Blackfriars.

Load factor = 73.4 per cent.
Running plant load factor = 80.1 per cent.
Average power factor = 0.98 lagging.

higher overall efficiency although it has certain disadvantages, especially as regards the increased air-delivery temperature and the danger of drawing in gas through leaky street tubes, and both these matters have to be specially guarded against. For the house tube systems, described below, rotary blowers maintaining a constant flow of air through the tubes are extensively used and are very economical in use.

The pneumatic power is employed for connecting head telegraph offices with branch offices by means of "street" tubes of $1\frac{1}{2}$ in., $2\frac{1}{2}$ in., or 3 in. internal diameter, and for distribution purposes in the buildings themselves by means of "house" tubes of $1\frac{1}{2}$ in. or $2\frac{1}{2}$ in. internal diameter, the carriers in which the messages are placed taking one of the forms illustrated by the samples.

For "up" tube working a vacuum of about 7 lb. below atmosphere and for "down" tube working a pressure of about 10 lb. above atmosphere have been employed. In actual practice about $5\frac{1}{2}$ horse-power is required to work a $2\frac{1}{2}$ -in. tube one mile long continuously at 10 lb. pressure, the time occupied in the transit of the carrier being $2\frac{1}{2}$ minutes. For the same speed with vacuum working the horse-power required would be less in the proportion of 1.83 to 1.

satisfactory results. The sliding portion of the switch merely consists of two sections of tube, either one of which by operation of the switch is brought into line with and forms part of the main tube while the other section is free for the insertion or discharge of a carrier.

On street tubes block-signalling apparatus is employed, and on long tubes an automatic regulator is also employed which gives a clearing signal after a fixed interval of time and provided clearing signals are being received from the receiving station; by this means the time interval between carriers in a tube is easily controlled, and although a tube is carrying a continuous stream of carriers the effect of a blockage is minimized and is limited to a definite number of carriers. In many cases three offices which may be some distance apart are served by one tube; in this case an intermediate switch is fitted at the intermediate office, and in some cases coloured carriers are used to distinguish between traffic for the intermediate and the terminal offices.

In the case of two long tubes to the West End of London, on which the traffic is at times very heavy, special arrangements have been made for accelerating the working during the busy hours. The "up" and "down" tubes are looped together at the distant end through a 3-way rotary switch, and a pressure of 20 lb. per sq. in. is applied at one end of the loop and a vacuum of 8 lb. per sq. in. at the other.

The particulars of these tubes and the transit times are as follows:—

Length in yards	Diameter	Transit Time (Average for New Carriers, in seconds)	
		Up	Down
4,180	3 in.	375	464
3,000	3 "	245	336
3,609	2½ "	364	480
4,051	2½ "	452	535

Such an arrangement is of course only justified by the extremely heavy traffic and the high capital cost of the tubes; during the slack hours the normal pressure of 10 lb. per sq. in. is used.

For short street tubes and house tubes through which the traffic is continuous over considerable periods a system has been used in which the tubes are connected in series and a current of air is maintained through them by means of an electrically-driven rotary blower. The carriers are inserted in an orifice closed by a flap and are automatically discharged at the terminal through a flap; no signalling apparatus is required, the carriers moving in a stream at close intervals. A modification of this system to adapt it for intermittent working includes a remote-control starting switch to enable the motor-pump in the power room to be started from the operating room. As an indication of the economical nature of this system the power consumed in maintaining the passage of carriers at intervals of 5 to 10 seconds in a 1½-in. tube system of a total length of 650 ft. is only ½ kw.

Pneumatic power has recently been employed in a trunk telephone exchange for distributing, between certain points in the exchange, the tickets on which are entered particulars of the trunk connections required. Instead, however, of using tubes of circular section and carriers such as have been described above, the tubes are of rectangular section 2½ in. × ¾ in. and the tickets are propelled through them by means of a folded end at right angles to the remainder of the ticket, which practically serves as a sail when pressure is applied and which also enables the ticket to be drawn through the tube when a vacuum is applied. The tickets are conveyed from various operators to a distributing centre by vacuum, and are thence dispatched by pressure to other operators; at the distributing centre the tickets are discharged without destroying the vacuum by means of two electrically-driven rollers which except during the passage of the ticket are kept in contact by springs on their axes—the tickets are also inserted in the vacuum tube by means of an arrangement which reduces the opening to the atmosphere to a minimum. The dispatch from the distributing centre is effected by placing the ticket in a receptacle and afterwards applying the pressure by means of a valve actuated by a plunger which also lights a signal lamp. The ticket on being discharged strikes a lever which breaks a contact which has the effect of de-energizing the electromagnet in connection with the pressure valve, and so cuts off the pressure from that particular tube and extinguishes the lamp.

A full and illustrated description of the system, which has been installed by the Western Electric Company, will be found in an article by Mr. H. P. Brown in the *Post Office Electrical Engineers' Journal*.*

IV. LIFTS.

While it has been the practice for any hydraulic lifts in post office buildings to be installed by H.M. Office of Works, the Post Office Engineering Department is responsible up to the present time for the installation and maintenance of no less than 207 electric lifts (representing a total motor capacity of 1,669 b.h.p.) which are operated from every kind of electrical supply and embody almost every system of control. While in most cases a continuous-current supply has been available we have in the new King Edward Building an installation of 12 lifts of from 5 cwt. to 5 tons capacity operated by three-phase current at 440 volts and 50 periodicity as regards the main circuits, and by continuous current at 210 volts as regards the control circuits.

At the Sheffield Head Post Office we have three lifts operated by a two-phase 50-period 200-volt supply, the controllers (which are of the up, down, and stop push-button and car-switch type) working from the same supply.

At the Islington Postal Stores and the Northern District Post Office there are 10 lifts working on a single-phase 50-period 410-volt supply, a separate continuous-current supply at 100 volts being provided for the control circuit. Solenoids for use on alternating-current circuits have been greatly improved both as regards efficiency and silent working since the lifts at the Postal Stores were erected, and we have installed 5 lifts at the New Money Order Office, operated by means of Bandy motors from a single-

* Vol. 4, p. 209, 1911-12.

phase supply at 440 volts and 50 periodicity, the controllers being worked from a supply at the same periodicity but at 200 volts.

In certain offices we have small lifts working on single-phase alternating-current supplies of 100 periodicity. The last-named supply, however, is naturally unsuitable for lift

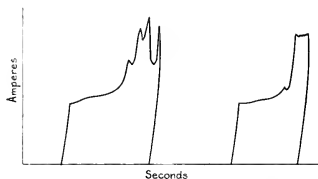

FIG. 4.

FIG. 4A.

operation, and while the existing installations have been made to work fairly satisfactorily it is not desirable to install lifts on a supply of this description if it can possibly be avoided.

The general lines on which lift installations are carried out are well known to members, and it would not be

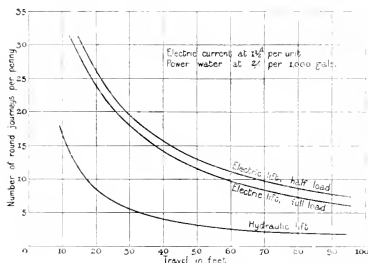

FIG. 5.—Curves showing comparison between Electric and Hydraulic Lifts of 20 cwt. Capacity and Speed of 200 ft. per minute. Electric supply 3-phase 50 ~ 440 volts.

necessary, even if space permitted, for me to describe them in this paper, but it may be of some value to refer to results of experience which are taken into consideration when deciding whether an electric or an hydraulic lift should be installed in any particular case where both sources of power are available.

The capital cost of an electric lift is usually greater than that of an hydraulic lift except in the case of a very long travel. The average maintenance cost of an electric lift is not likely to be so great as that of an hydraulic lift, but for all practical purposes they are taken to be about the same. The cost of electric and hydraulic power varies considerably in different localities, but it is of course a simple matter to take proper account of these factors.

With regard to safety, it is considered that the possibility of an accident is reduced to a minimum with modern electric lifts, the safety appliances of which include electrical and mechanical interlocking of gates, interlocking between main and control circuits, main and control limit switches, guide grips to hold the cage in the event of a breakage of the ropes, and the provision against running away by the braking action of worm and wheel, supplemented in certain cases by a suitable emergency brake. The author believes he is right in saying that there has not been a single fatal accident with an electric lift installed by the Post Office.

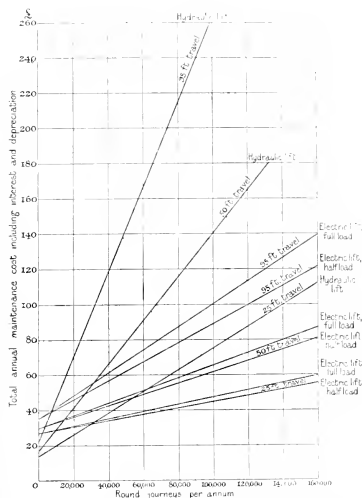

FIG. 6.—Six per cent on Capital Outlay allowed for Interest and Depreciation. Cost of electrical energy = 14d. per Board of Trade unit. Cost of hydraulic power = 2s. per 1,000 gallons of water. Electric supply 3-phase 50 ~ 440 volts.

The current taken by the electric lift is proportional to the load when balanced for no load, whereas the amount of water taken by the hydraulic ram is the same whatever the load. As a matter of fact it is usual to balance the cage of the electric lift for half-load, under which condition the power taken is merely that required to accelerate and overcome friction. With a view to economy at variable loads hydraulic lifts have been fitted with two rams, but this arrangement has not, so far as the author is aware, met with much success. The amount of water taken by an hydraulic lift is independent of the number of stops, whereas each time an electric lift is started there is a waste of power which is a considerable portion of the total power required for a short journey.

The greater the number of stops and the shorter the travel between floors, the less favourable is the case for the electric lift as regards the cost of operation. Careful attention to the design and adjustment of the control gear is desirable in this connection.

Fig. 4 shows a "current-time" curve obtained by means of a recording ammeter for a 15-cwt. goods lift working between floors to ft. apart with a controller as supplied by the maker. Fig. 41 shows the corresponding current-time curve after the controller had been adjusted so as to reduce the waste of power. The result of adjustment was that without increasing the maximum current the time taken for a complete up and down journey was reduced by 24 per cent while the energy consumption was reduced by 30 per cent.

In order to co-ordinate as far as possible the many factors referred to above a series of careful tests have been carried out on electric and hydraulic lifts of similar capacity when working under various conditions as regards length of travel. Examples of the results obtained are

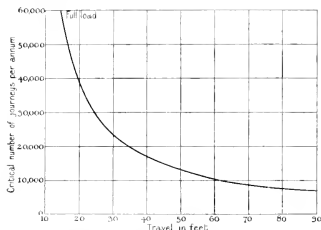

FIG. 7.—Curve showing Comparison between Electric and Hydraulic Lifts of 20 cwt. Capacity and a Speed of 200 ft. per min. Electric supply 3-phase 50 \sim 440 volts.

shown in Fig. 5. The number of journeys per penny is plotted vertically, and the distance between the floors is plotted horizontally. From these curves it is an easy matter to arrive at the results which would be obtained for similar lifts with different lengths of travel and with different prices for current and water.

Fig. 6 shows the annual cost, including interest and depreciation, maintenance, and cost of current, plotted with reference to the number of round journeys per annum. These curves show clearly the critical number of journeys for which the annual charges in respect of electric and hydraulic lifts of a particular size are the same under different conditions of travel. To put this information in a more useful form Fig. 7 shows the critical number of journeys per annum plotted with reference to the length of travel for the same size of lift and under the same conditions as regards price of current and water.

V. CONVEYERS.

Sorting Office.—The sorting offices in the larger postal centres offer a wide but by no means an easy field for the ingenuity of the designer of mechanical appliances. Before

proceeding to describe what has been done in this direction it will be well to state briefly the processes through which a letter passes in one of these offices—choosing a simple case of what is known as "outward sorting" for the purpose of explaining the objects to be kept in view.

Letters inserted in the posting boxes at the head post office, or brought in by the postmen from the local pillar boxes, say at one of the principal provincial towns, are deposited on tables and "faced" by picking them up and placing them so that the address sides all face one way with the stamp in the lower left-hand corner. The faced letters receive the locality and time impression and have their stamps obliterated. They are then taken to the primary sorting tables and sorted into 20 or 30 "roads," each of which may include several towns or districts. The letters for each road are next taken to secondary sorting or dispatch tables where they are further sub-divided and made up into bundles which are placed in bags in which they are conveyed to the railway stations. It should be stated that bags of mail matter received from the railway stations similarly pass through a process of "inward sorting" before delivery, but the above explanation of "outward sorting" will probably suffice.

It will be understood that while there are certain selective processes which can only be carried out by human agents there is scope for mechanical transportation between the processes, and the following are examples of what has been done.

Band conveyers have been employed to convey letters and packets, as they are dropped into the posting boxes, to the facing tables.

At King Edward Building (London) a ropeway has been used to convey baskets of letters posted in the Newgate-street boxes to the vicinity of the King Edward-street boxes, whence the baskets are taken up to the sorting office on the floor above by means of a band conveyor.

Slow-moving bands erected along the centre of the facing tables are used for conveying batches of faced letters to the end of the table where the stamping is done.

The stamping and obliterating in all the larger offices is now done by means of electrically-driven stamping machines which deal with 600–800 letters per minute.

The principal elements of one of these machines include:—

- (i) A magazine in which the faced letters are placed by hand.
- (ii) Driving rollers for feeding the letters forward into the machine.
- (iii) A separating device to prevent more than one letter at a time from entering the machines.
- (iv) A die and impression roller and inking pad.
- (v) The mechanical stacker into which the letters finally pass, and which prevents their becoming detached, or otherwise disarranged in a manner which would be prejudicial to expeditious sorting.

Band conveyers are employed for transporting made-up baskets and bags to the loading platform. It should be noted that a different form of delivery is required for bags and for baskets, the former being allowed to fall on the platform, or, in the case of parcel bags, into a suitable chute, while the baskets are best received and brought

to rest on gravity rollers. All the conveyers which have been installed are electrically driven.

So far the appliances which have been described are those which have been fitted in existing offices in order to facilitate operations carried out in accordance with existing ideas.

The difficulties in design involved in adapting these appliances to these operations in old offices arranged and constructed without reference to their embodiment have of course been very considerable.

Experimental Sorting Apparatus.—Experiments have recently been made which aim at the mechanical transport of correspondence practically right through an office, from the posting boxes to the dispatching tables, and thence to the loading platform.

The practicability of conveyers from posting boxes to facing tables has already been proved, and bands are also in use carrying faced letters from one end of a facing table to the other, but the experimental installation provides for the stamping machine at the end of the table being fed mechanically instead of by hand.

In framing the complete scheme it was assumed that all correspondence would be received on a platform at one end of the sorting office adjacent to the facing tables, and at this platform one man is required to watch and adjust the flow of work along the facing tables, the letters, etc., being carried by bands above these tables and deflected at will (through shoots) to the facers at their various positions along the tables. At intermediate positions (between these overhead shoots) there are openings in the table through which the newspapers and packets picked out from the general correspondence are dropped on to the return half of the band which is carried beneath the table and deposits them at the end of the table for separate treatment.

The facing table has along its edge a series of slots formed by smooth sheet-iron or wood, through which the facers drop the letters in an upright position on to a running band below the table. Each of these individual slots forms a "siding" leading to a main slot which runs from end to end of the table and into which the letters pass without "fouling." At the end of this main slot the letters are mechanically separated and fed direct into the stamping machine, and then "stacked" by the mechanical stacker which forms part of the machine.

As an alternative arrangement each small slot or "siding" is fitted with its own stamper, consisting of an impression roller and die. By this means noise is reduced, there are fewer failures, and it is possible to fit a mechanical counting device to each stamper so that the output of each facer can be ascertained. On the other hand the periodical changing of so many dies causes some additional work. The letters are automatically stacked at the end of the table.

We have so far followed the letters through the facing, stamping, and stacking processes. At this point attendance is required to transfer the stacked correspondence into boxes which, when filled, are carried away by a specially designed chain conveyer to selected points on the primary sorting table. The boxes travel along the back of the sorting table and are delivered automatically at the side of the sorters, being deflected on to moving platforms which move out to meet their respective boxes.

As the sorters empty their boxes they send them back to

the machine (empty) by a similar conveyer, and the officer there refills them in turn and places them again (full) on the conveyer. As the conveyer discharges them only at the particular points from which they have been returned as empties, the sorters are kept supplied without any trouble. The primary sorting is done through a grid (*i.e.* through vertical slots) on to a wide band running below the table. For each division or "road" a slot is provided, 1 in. wide, and a sorter can have as many as 24 divisions easily within his reach.

From the primary table, the band runs to the dispatching tables, and at each "road" the slot carrying the correspondence for that particular "road" is turned outwards to the front edge of the table so as to discharge the correspondence proper to that road, and at this point it is stacked again by a mechanical stacker ready for the secondary sorting. It will thus be seen that the correspondence passes direct from one process to the next without any delay such as is inherent to hand collection.

The experimental apparatus has been installed at Liverpool Post Office, and the preliminary trials have been satisfactory and indicate a substantial saving of time over the existing methods. Improvements are at present being made in one or two points of detail and it is, of course, too early to say how far these new methods can be generally applied. The whole of this experimental apparatus is electrically driven.

It will have been gathered that the form of conveyer which has been most extensively applied in sorting offices is the moving band. While not so well adapted as other forms for routes subject to lateral variations or for selective operations, it has very great advantages for point-to-point routes, and vertical variations in route can be overcome to a considerable extent.

The fact that it is continuous and that every inch is available for the load gives it an exceedingly large capacity, while the facts that it is comparatively noiseless and safe in operation, that it is readily enclosed, and that it can be economically driven by means of an electric motor through worm, spur, belt or chain gear, render it particularly suitable for the localities in which it has to be installed.

With regard to the economical results obtained it should perhaps be stated that the installations are as a rule only authorized when it can be shown that the annual charges, including interest and depreciation, maintenance, and cost of energy are such as to show a saving as compared with the cost of labour displaced.

Telegraph Instrument Rooms.—In telegraph instrument rooms the problem has been how to displace boy labour by means of a mechanical appliance which would save time and which would meet the following conditions:—

1. The system of mechanical appliances should, as far as possible, be uniform throughout the instrument room and the control should preferably be concentrated at a central point.
2. The apparatus must be automatically selective as regards distribution to the operators, *i.e.* it must be possible to dispatch a telegram form to any desired point on any table. The forms must also be conveyed from any point on any table to the check table, but this is not a selective operation.

3. The dispatch of the telegram forms by the various operators should not involve any further break in the continuity of their work than is at present involved by the placing of the forms on the message baskets from which the boy messengers collect.
4. The apparatus must be silent in its operation, and moving parts must be arranged so as to obtrude to the smallest possible extent on the vision of the operators.
5. The gangways and the lighting of the instrument room should be interfered with to the smallest possible extent.

An experimental installation has been fitted at Birmingham. "Pick-up" carriers bring the incoming telegrams from the various operators' stations and drop them on to hand conveyers, which deliver them at the "check" table, whence they have to be distributed selectively to the operators who deal with the outgoing circuits. This selective distribution is effected by placing the telegrams on tablets arranged vertically in groups of 5 or 6 corresponding to the various stations on each table. The endless cord running between the "central check" and each table draws the selective carriers, the jaws of which are made to open and close by means of ramps, and so pick up the telegrams only from their proper tablets and similarly deliver them only at their proper stations. The carriers also pick up at the table stations and deliver on to the bands at the check table referred to above. The carrier installation has been supplied by Messrs. Lamson, while the band conveyers have been installed by the Post Office. The cord and band conveyers are driven by electric motors placed underneath a platform at the "central check."

VI. HEATING AND VENTILATION.

With certain exceptions the heating plant in the larger post office buildings is installed by H.M. Office of Works, but its maintenance is in the hands of the Post Office engineers, who now have some 600 installations to attend to, and who usually carry out any re-arrangements which become necessary from time to time. All cases of mechanical ventilation are dealt with by the Post Office Engineering Department.

Owing to the fact that in large sorting office buildings there is on one floor a large force of men whose bodies give off an appreciable amount of heat, and who are actively employed during certain hours of the day, while on other floors the clerical and other sedentary duties are performed by a comparatively scattered force, it will be evident that the heating and ventilation systems have to be very carefully designed. Almost every kind of heating system has been applied, including high-pressure hot water, low-pressure hot water with either boilers or calorifiers heated by live or exhaust steam when available, and an exhaust steam system with extractor pumps. The usual system adopted is the low-pressure hot-water system with or without forced circulation, according to the local circumstances, and with separately controlled radiators.

A description of the system of heating and ventilation installed at King Edward Building may perhaps be of interest. The heating of this building is carried out by some 400 radiators on the low-pressure hot-water system.

Where radiators are fitted against the outer walls ventilators are installed so that the fresh air is warmed on its way to the building. The water is heated in 12 calorifiers placed in six pairs in different parts of the basement. The calorifiers are provided with steam at 60-lb. pressure from boilers of the Lancashire type. The basement and sub-ground floor with total cubical contents of 1,300,000 and 1,400,000 cub. ft. respectively are provided with 16 ducts 8 sq. ft. in area, of which 12 terminate in fan houses on the roof of the sorting office block and the remainder on the roof of the public office block. The ducts are connected in pairs in the fan houses, and each pair is fitted with a fan having a capacity of 20,000 cubic ft. of free air per minute on the sorting office block and 9,000 cubic ft. of free air on the public office block. Fresh air enters the basement by means of staircases and lift wells and the sub-ground floor by the same means together with windows.

The ground-floor sorting office has a total cubical content of 1,270,000 cubic ft., and is provided with six ducts each of 4 sq. ft. area, of which four are connected to a fan on the roof of the sorting office block, with a capacity of 80,000 cubic ft. of free air per minute, and the remainder in pairs to fans, each having a capacity of 15,000 cubic ft. of free air per minute. Fresh air is freely admitted through windows and ventilating radiators.

These fans, which are of course electrically driven, will change the air of the various floors at a rate varying from a minimum as produced by unaided ventilation to a maximum forced circulation of 2½ to 3 changes of air per hour.

It is found during mild weather in the winter when the outside temperature varies from 48° F. to 55° F., that although an equable temperature of 60° F. is maintained in the building during slack periods, it is necessary to shut off the heating system at the busy hours (early morning and early evening) owing to the fact, referred to above, that the temperature is greatly increased owing to the increase in the number of men employed, and also to a slight extent from the electric lighting system (clusters of metal-filament lamps); otherwise temperatures exceeding 60° F. are obtained.

Considerable difficulty has been experienced with the ventilation of telephone exchange switch-rooms, owing to the high switchboards interfering with the natural circulation of the air. Most satisfactory results have, however, been obtained by installing suspended fans of the revolving type between the switchboards to circulate the air, in addition to fans in the windows for the extraction of air.

In one particular case where natural ventilation is difficult, an ozone plant has been installed with successful results.

VII. BAG CLEANING.

Several types of machines for cleaning mail bags have been tried, the most satisfactory results being obtained with the type installed at the King Edward Building. This plant consists essentially of two octagonal lattice work drums, about 10 ft. in diameter, revolving inside wooden casings connected to a filter by an air duct, which in turn is connected to a powerful blower that draws air through the drum and filter. The drum is opened at one side and the bags to be cleaned are inserted and the trap-

door closed, as is also the door in the outer casing. The drum, which is driven by an electric motor, is then set in rotation by means of belting through fast and loose pulleys, and revolves at a speed of 30 revs. per min. The cleaning is accomplished partly by mutual rubbing of the bags and partly by their dropping from the top to the bottom of the drum. The heavier particles, such as wax and string, fall into a hopper at the bottom of the casing and are collected in a sack. The lighter particles are drawn through the air trunk to the filter, which consists of an iron case divided into three partitions, each connected to the blower. Each partition contains eight filter hoses, the bottom of each being connected to the air trunk from the drum. Their upper ends are closed by an iron cover suspended from rocking levers. The fabric of these hoses is of such a nature that the dust is retained on the inside of the hoses. The rocking levers are connected with a mechanism which at fixed intervals automatically draws the hoses tight and then allows them to fall back again to the slack position, thus thoroughly shaking the dust from the fabric.

The hoses in each compartment are alternately cleared of the adhering dust at fixed intervals, the suction of the fan being cut off from the compartment in which the hoses are being shaken by means of a baffle which simultaneously opens a passage giving free access to atmospheric air. The latter enters the partition with more or less power according to the vacuum created by the fan and penetrates

although in a few cases it has been necessary to install oil or gas engines. With the exception of the generators this plant follows the usually accepted practice and does not call for any special description; the generators are, however, specially designed to give silent working when supplying the telephone-exchange circuits direct without any battery in circuit. Such conditions are very difficult to meet, and until recently satisfactory machines could only be obtained from America. Their manufacture has, however, been developed by two or three English firms, and satisfactory English-made machines can now be obtained. Their chief features are ring-wound armatures with a large number of commutator segments, uniform distribution of the field, good balancing both mechanically and electrically, good commutator surface and a special type of high-conductivity brushes; large choke coils of special design are also used in conjunction with the machines. The machines are built in sizes from 1 to 40 kilowatts. As showing the extent of this work the author might mention that upwards of 40 exchanges had to be equipped very rapidly in connection with the taking over of the National Telephone Company's system.

IX. ELECTRIC LIGHTING.

The extent to which electric power is used for the lighting of post office premises will be gathered from the following table showing the equivalent number of 8-c.p. lamps connected for the past five years:—

At end of—	Total No. of Offices Lighted Electrically	Total No. of Incandescent Lamps in 8-c.p. Equivalents			Increase on Previous Year	
		Metal Filament	Carbon	Metal Filament and Carbon	Offices	Lamps (Metal Filament and Carbon)
1908-9	427	31,164	120,148	151,312	—	—
1909-10	469	49,836	115,105	164,942	42	13,630
1910-11	530	197,320	58,740	256,060	61	91,118
1911-12	592	284,559	37,616	322,175	62	66,115
1912-13 (including ex-N.T.Co.'s Offices)	850	380,439	20,345	400,784	258	78,600

the hose from the outside, thus materially assisting the mechanical shaking in the removal of the dust. The dust falls to the bottom of the filter into a screw conveyor and is fed into a hopper from which it is collected in a sack. This cleaning operation occurs about every five minutes in each partition separately, and as there are three compartments the exhausting and filtering process is never interrupted. The charge of bags is rendered completely clean in about 20 minutes, the total capacity of the plant being about 400 bags per hour.

VIII. TELEPHONE EXCHANGE POWER PLANT.

A large amount of plant is in use in connection with central-battery telephone exchanges, motor-generators and accumulators being almost exclusively used for this purpose

The consumption of energy has not increased in the same proportion owing to the introduction of metal-filament lamps; in fact, an annual saving of not less than £8,000 has been effected by the substitution of metal-filament for carbon-filament lamps after allowing for the increased costs of renewals; approximately 4,300 kw. is now absorbed for lighting purposes.

Up to the last few years the lighting in sorting offices and in telegraph and telephone instrument rooms was carried out by means of arc lamps, or by carbon-filament lamps placed singly in close proximity to the points at which the work is done. A system of general lighting by means of clusters of metal-filament lamps contained in fittings with opalescent shades has now been adopted

for the larger offices, and is found to have the following advantages :—

1. A soft well-diffused light is obtained with comparative absence of shadow and eye-strain.
2. The lamps are not subject to vibration to the same extent as when fixed to the sorting or other fittings.
3. The lighting installation is practically independent of the position of the sorting fittings and re-arrangement of the latter does not therefore necessitate alteration to the former.

The lighting installation can also be completed without waiting for the sorting fittings to be supplied, which has proved an important point in cases of urgency. To obtain the full advantages of this system of lighting it is very desirable that walls and ceilings should have dull white or cream surfaces, and any large windows should be provided with light blinds.

As the result of careful experiment it has been found that the amount of illumination in foot-candles which it is necessary to provide for various purposes, is as shown in the following table :—

Part of building	Max. foot-candles	Min. foot-candles	Average foot-candles	Where measured
Sorting (letters and parcels)	3'0	2'0	2'5	3 ft. above floor
Instrument rooms (special)	2'5	2'0	2'25	Table height
Ditto (ordinary)	2'0	1'5	1'75	Table height
Loading platforms	1'5	1'0	1'25	3 ft. above floor
Offices for clerical work	2'0	1'0	1'5	Desk height
Stairs, passages, etc.	0'75	0'3	0'52	3 ft. from floor
Retiring rooms	1'0	0'5	0'75	Table height
Telephone exchanges (trunk)	2'0	1'0	1'5	{ Max. at Desk
Ditto (ordinary)	1'5	1'0	1'25	{ Min. at Switch Ditto

The provision and measurement of illumination on the basis of the number of foot-candles at the level at which the work is carried on has greatly facilitated the investigation and adjustment of complaints of inefficient lighting, compared with the old basis of candle-power per square foot of floor area, as it is no longer so easy to suggest that the "square feet" or the "candle-power" are in the wrong place, or that the latter is insufficient.

In large sorting offices the required illumination has been obtained by clusters of 3 (or 4) 100-c.p. lamps suspended at a height of 13 ft., and spaced at intervals of 18 ft. In sorting offices where there is not sufficient head-room for the above arrangement, clusters of three 50-c.p. lamps have been used, suspended at a height of 10 ft. 6 in. and spaced at intervals of 13 ft. In small sorting offices single 100-c.p. lamps fitted with Holo-phane shades have been used with advantage, suspended at a height of 10 ft. 6 in. and spaced at 10 ft. 6 in. intervals.

In telegraph instrument rooms, where it is particularly necessary and rather more difficult to eliminate shadows, clusters of three 50-c.p. lamps, placed as in the sorting offices, are employed.

Screwed conduit is now used in preference to wood casing for internal wiring.

X. POST OFFICE (LONDON) RAILWAY.

As members are doubtless aware, powers have recently been obtained to construct an electric railway for purely postal purposes between the Paddington District Post Office in London Street and the Eastern District Post Office at Whitechapel, with intermediate stations at the Western District Parcel Office, at the Western District Post Office, at the Western Central District Post Office, at Mount Pleasant Sorting Office, at King Edward Building Post Office, and at Liverpool-street Station.

The railway contemplated under the present scheme is indicated by the full lines in Fig. 8, while the ultimate extensions contemplated are shown by the dotted lines. Between the stations the railway will consist of two tracks each 2 ft. gauge, one for east-bound and the other for west-bound traffic, and contained in a single tunnel of 9 ft. internal diameter.

A complete scheme has been worked out in detail in collaboration with Mr. Dalrymple-Hay. The latter is responsible for the tunnelling, while the Engineer-in-Chief of the Post Office is responsible for the equipment.

Three of the stations, viz. the Western Central District Office, Mount Pleasant, and King Edward Building, will form important junctions when extensions to the north and south are undertaken.

It is intended that the trains should be operated without drivers on the remote-control system.

The present is clearly not a convenient or proper time to give a detailed description of the scheme which, whilst it will form the basis of invitations to tender, will leave the way open for alternative proposals as regards the electrical equipment. A brief reference to the main outlines of the *model scheme* may, however, be of interest at this point in view of the information which has already been published.

A station will consist of an island platform arranged in two sections, between which will be placed a control cabin and the lifts and conveying appliances that have been specially designed to suit the different classes of postal matter which have to be dealt with between the station platforms and the postal buildings above. This is the general design of station which has been adopted in all cases, the arrangement of the tracks and of the conveying appliances being adjusted to suit the requirements at the different points.

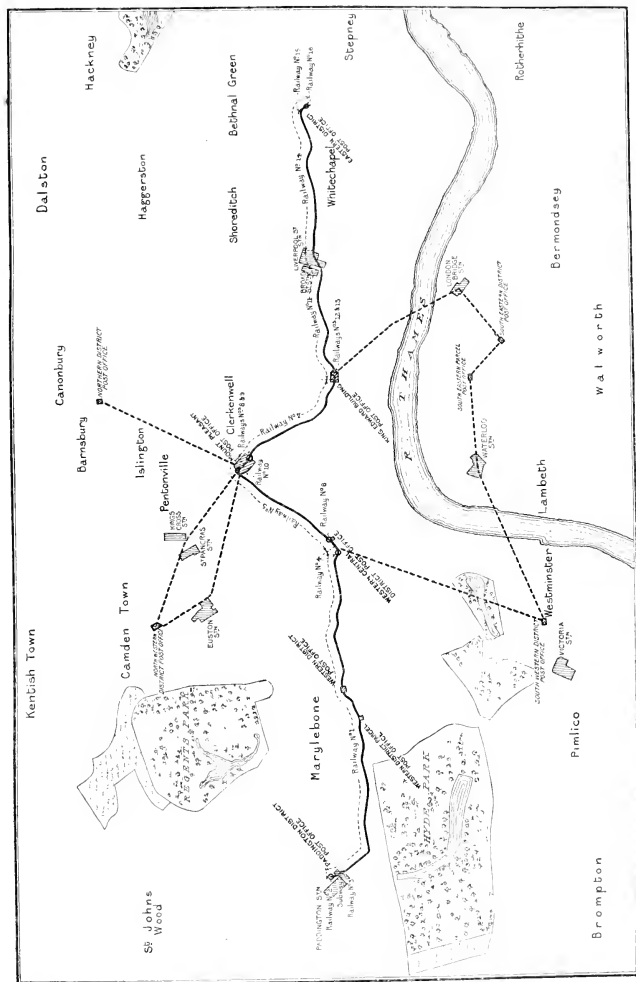

FIG. 8.—Post Office (London) Railway.

It is proposed to operate the wagons or trains by three types of current, which it will be convenient to refer to as high speed (H.S.), intermediate speed (I.S.), and low speed (L.S.). Between the stations H.S. current will be applied. At the approach to a station the wagons will pass over a short gap in the conductor rails and brakes (which will be electrically released when the train is taking current and applied when the train is not taking current) will be applied. The next section of conductor rail will normally be "dead," and will be of such a length as to allow the wagon to come to rest, the brake remaining on.

In the case of a wagon which is required to stop at the station, a L.S. current will be applied to this brake section and the train will move to the station platform, and will finally be brought to rest owing to the application of the brakes when it reaches its sub-section of the station platform, the conductor rails of that sub-section having been made "dead" for its reception. In the case of a through train I.S. current would be applied to the brake section, and the wagon would run at this speed through the station, would pass over a short gap in the conductor rails, and then without a stop on to the sections of the track energized by H.S. current. In the event of its being possible to accept, without delay, either a stopping train or a through train, the braking section or a certain portion thereof would be energized with I.S. or L.S. current respectively before the train reached that section, in which case the train would merely be retarded down to the speed corresponding to the current applied, and would either pass up to the platform or straight through the station. A wagon will be dispatched from the station by making alive the conductor rails of the sub-section on which it has been standing with I.S. current, if it is being sent on to a main line, or with L.S. current for shunting operations.

Wagons will be moved into the sidings and brought to rest in certain sections in the same manner as at the platforms, and a device will be provided for automatically reversing the connections of the motors, when desired, just as they are coming to rest, so that they may move off in the opposite direction when current is applied to withdraw them from the sidings. Means will also be provided for holding the brakes off without applying driving current to the motors, so that the wagons may readily be coupled up to form two or three car trains. When coupled up in this manner it will be arranged that by means of a train cable and certain switches the shoes of the rear wagon only will collect current from the conductor rails, but the motors on all wagons will be operative and share in the driving of the train. This arrangement will overcome difficulties which would otherwise arise in dealing with both single wagons and trains at gaps, braking sections, and dead sections at the platforms and in the sidings.

It should here be made quite clear that it is not intended that the control of the wagons as they come to rest in, or pass through, the station should need the continuous attention of the switchman. The position and destination of each wagon will be notified to this officer, who, by means of small levers in the cabin, will set points for the particular route desired and will energize certain sections of the conductor rails with the appropriate current. The wagon will then come to rest at the proper section of the platform, or will run through the station without further attention. The operation of the points will be

interlocked with the application of the current, and there will be a complete interlocking arrangement between the different routes.

The proposed system of control may be briefly described as being generally similar to the power-operated point and signal systems adopted for modern railway undertakings, but with the signal element replaced by the application of current to the track. It is considered that it is only by such a system of complete interlocking that a remote-control electrical railway of this scope can be safely operated.

Between stations the conductor rails will be divided into sections, and while running between stations and before coming within the control of the switchman the wagon will itself render each section "dead" as it leaves it, and will make it "alive" again on entering the next section but one, that is to say, there will always be a "dead" section between adjacent wagons or trains.

Means will be provided for indicating not only the position, but also the destination of approaching trains, and so enabling the switchman to arrange for their reception either separately or simultaneously as the case may be, being protected against mistakes by the interlocking arrangement which has been described above.

Possibly at a later stage a separate paper may be read on this railway and its equipment, as the problems which have presented themselves for solution have certainly proved very interesting and in many respects novel.

XI. ELECTRIC TRUCKS AND VANS.

The electric railway is not the only direction in which the use of electric traction for postal purposes is being introduced. With a view to reducing human labour and the delays connected with double handling, trials are at present being made with an electric truck equipped with an Edison battery.⁶ This truck, which weighs only about 25 cwt. including a load of 10 cwt., is intended for use more particularly at offices that are in close proximity to railway stations, and can ply between the sorting office and the mail vans, the control being sufficiently safe and flexible to meet the conditions of a crowded platform, while slopes as steep as 1 in 10 can be negotiated.

Trials of the truck, which is equipped with 42 B4 cells, have been carried out on level wood-block flooring (the wheels having solid india-rubber tyred wheels 15 in. diameter) over a rectangular course 824 ft. per circuit at full speed (5 to 7 miles per hour), and at about half-speed (3 to 4 miles per hour) over alternate circuits and with a stop at the end of each circuit, and the following results have been obtained:—

Total weight of truck, load, and driver...	26 cwt.
Voltage before run (half battery) ..	30 volts
Voltage after run (half battery) ..	20 "
Total number of journeys... ..	160 "
No. of miles... ..	25 "
No. of units used for charging ..	73 "
No. of watt-hours per ton-mile ..	225 "

Experiments are also being made with electrically-equipped vans for collecting purposes.

⁶ *Electrical Review*, vol. 73, p. 342, 1913.

XII. CONCLUSION.

While the above examples do not exhaust the various applications of power for the Post Office, they will probably suffice for the purposes of this paper. Nearly all these applications involve the employment of electricity, without which many of the appliances could not have been devised or employed in the places where they are required.

The author wishes to express his thanks to the Engineer-in-Chief, Mr. Slingo, for permission to read the paper. He also desires to acknowledge the assistance which he has received in its preparation from Messrs. W. H. Powell, H. V. Cornish, J. R. Matthews, and E. H. Walters, who are closely associated with the work which has been described.

ELECTRICITY SUPPLY OF LARGE CITIES.

By Professor G. KLINGENBERG, Dr. phil.

(Address delivered before THE INSTITUTION, 4th December, 1913.)

Electricity is now universally acknowledged to be the most suitable form of energy supply for large cities, and apart from the convenience and reliability, its wide range of application makes it superior to gas, which 20 years ago had no competitor in this field. Although electricity was originally intended exclusively for lighting, its extensive application for power soon followed, and in many towns the power demand nowadays exceeds the lighting consumption. Electricity has introduced a radical change in the means of communication, by permitting the successful introduction of rapid transit systems (underground and elevated railways) which are regarded as indispensable in large cities at the present day. A further field has been opened in its application to heating and cooking. The fact that electricity, notwithstanding its obvious advantages, has hitherto been unable to drive its competitors entirely out of the field, is solely due to the difference in price for the same amount of energy, arising from the cost of electricity in some of its applications.

Any reduction in price therefore results in an increased use, and it may be said without exaggeration that there would be no demand for other forms of energy if all electric supply undertakings would fully recognize the advantages which our present-day knowledge and experience place at their disposal, and if they could rid themselves of the restrictions originally placed upon them in the supposed interests of the consumer, which restrictions are now very often found to be a hindrance to both consumer and producer.

It is the purpose of the present Address to explain the nature of these conditions and draw attention to those factors which would contribute towards a reduction in the cost of electricity and facilitate its more extensive employment.

With reference to existing conditions, I have confined myself to three examples which I consider to be typical. The material at my disposal enabled me to extend my investigations to details which will be of value when forming an opinion on the entire question. The cities selected are:—

Berlin—Berliner Elektrizitätswerke,
Chicago—Commonwealth Edison Company,
London—the municipal authorities and authorized supply companies in and around London.

The figures are based on the following years:—

Berlin	1911-12
Chicago	1911
London	1910-11

HISTORICAL DEVELOPMENT OF ELECTRICITY SUPPLY.

BERLIN.

In Berlin the electricity supply began with the purchase and operation of generating sets by commercial undertakings solely for their own requirements, and without intention of selling energy to outside consumers. This system was found to be convenient as it was not necessary to lay conductors in the streets, and as complete independence of municipal authorities was possible. A number of these so-called "block stations" still exist, their combined output being estimated at nearly 40,000,000 kw.-hours per annum.

The Berliner Elektrizitätswerke alone formed an exception in this respect; they were intended from the outset to supply current to outside consumers. In their contracts of the years 1888, 1899, and 1907 they obtained the right to use the streets, etc., upon the condition that they supplied all the electricity required for any purpose within the city of Berlin. They were accorded permission to generate electricity in the interior of the city, and to supply current to the city from outlying power stations. They were further authorized to supply current outside Berlin, on the condition, however, that the city plants as well as those outside the city within a radius of 30 kilometres (about 20 miles) could be taken over by the city authorities upon the expiration of the contract (1915). In consequence of the permission granted to supply current within any desired radius of Berlin, the Berliner Elektrizitätswerke were able to form a new supply area beyond the Berlin boundary, and to take financial interest in new undertakings. The tariffs are subject to the approval of the city authorities, who have decreed that the price at which the current is supplied must be reduced when the net profit exceeds 12½ per cent on the share capital. The city also participates in the profits, and receives 10 per cent of the company's gross income, and half the net profit after 6 per cent has been paid on the share capital up to M.20,000,000, and again half the profit left after paying

4 per cent above this amount. The sum paid out in this manner during the past financial year, for example, was M.7,184,000 (£350,000), which considerably exceeded the dividend paid on the company's share capital of M.64,100,000 (£3,150,000).

The development of the Berliner Elektrizitätswerke may be seen from the following figures for the energy sold :—

1900-1	Energy sold =	60,700,000 kw.-hours
1905-6	"	= 126,200,000 "
1910-11	"	= 192,100,000 "
1912-13	"	= 244,300,000 "

Although the city has formally notified the Berliner Elektrizitätswerke of its intention to exercise its rights to take over the whole concern in 1915, no definite decision has yet been reached.

The system of feeders of the Berlin electricity supply, the power stations, sub-stations, and feeder circuits (three-phase cable 6,000/10,000 volts) are shown in Fig. 11. The distribution in Berlin itself is on the continuous-current system throughout, with the exception of the suburbs and a section of the city in the north, which are fed directly with three-phase current.

Apart from the Berliner Elektrizitätswerke and the above-mentioned block stations a number of separate traction power stations exist, which supply energy to the underground railways and a part of the tramway system.

CHICAGO.

The Chicago electricity supply originated in a large number of small supply companies (approximately 36) which were amalgamated between the years 1892 and 1906 to form two large companies, viz.:—

The Chicago Edison Company,
and The Commonwealth Electric Company.

In 1907 these two companies were amalgamated under the title :—

The Commonwealth Edison Company.

All the small power stations have been shut down since then, and the whole supply is now obtained from four large power stations.

The concession extends over a period of 50 years, dating from the year 1897, and it stipulates the maximum rates to be charged by the company, and a payment of 3 per cent on the annual gross receipts to the city.

The development of the company may be seen from the following figures for the energy sold :—

1900	Energy sold =	33,700,000 kw.-hours
1905	"	= 93,000,000 "
1910	"	= 550,000,000 "
1912	"	= 712,000,000 "

The sub-stations are fed with three-phase current at 9,000 volts, 25 cycles, and in part at 20,000 volts, 60 cycles. The distribution in the interior of the city is on the continuous-current system, while in the outlying districts three-phase current at a frequency of 60 cycles is adopted.

LONDON.

If I understand the history of electricity supply in London correctly, it began, as in the case of Chicago, with a number of private companies. Their development was hampered, however, in the earlier stages by legal restrictions which limited the concessions to a period of 21 years and divided the electricity supply of the city into a number of districts corresponding to the administrative divisions, without taking into account the natural development of the distribution system. Every authorized supply undertaking was obliged to erect its own generating station and to lay out its own distributing network. An amalgamation of the different concerns was therefore out of question until in 1908 the original Act was modified by a new Bill. Since that time constant endeavours have been made to combine the numerous companies, to centralize the generation of energy, and to standardize the different distribution systems as far as possible.

DISCUSSION OF THE FACTORS DETERMINING THE COST TO CONSUMERS.

It has already been mentioned in the introduction that the development of the electrical industry in large cities is chiefly dependent upon the price of electrical energy, and I now propose to discuss the factors which determine this price.

Cost of plant.—The specific cost of the plant, i.e. the cost per kilowatt installed, should be mentioned in the first instance. As each kilowatt installed is only capable of supplying a given number of kilowatt-hours, the increase of cost will be in proportion to the capital expenditure per kilowatt, provided that other conditions remain unaltered.

A distinction must be made here between the cost of the power station and that of the network. In the power station the cost per kilowatt decreases rapidly as the size of the generating sets increases, or the more the generation of energy is centralized in large power stations. For works with modern generating sets of 10,000-kw. capacity the installation costs are found to be approximately £15 per kilowatt, whereas for units of 20,000-kw. capacity they only amount to one-half of this sum. Bearing in mind that for large cities outputs of several hundred-thousand kilowatts are required, units of less than 20,000-kw. capacity are obviously unsuitable and too expensive for this purpose, and the installation of 30,000-kw. sets appears to be fully justified. In consequence of this development the specific cost of power stations has fallen in about 10 years to nearly a quarter of its former value.

The conditions are not so favourable, as a rule, for the network. When the amount of energy that can be transmitted is increased by using cables of larger sectional area, the economic limits are soon reached, since the permissible specific load on a conductor, and therefore its effective utilization, decrease as the sectional area is increased. On the other hand the idea of extended centralization seems to have the reverse effect on the cost of the network, since this cost is increased by using longer feeder cables without any direct gain being secured as regards the network itself.

It is, nevertheless, also possible to economize on the capital outlay of the distribution system. In this connection the use of higher working voltages should first be mentioned. The customary feeder cables for pressures

of 6,000 to 10,000 volts no longer meet present-day requirements in large cities. The additional cost of transformation in the power station when the cable pressure exceeds 10,000 volts is counterbalanced, even in the case of short distances, by the saving effected in the cables. Whenever extensions are contemplated, pressures of 20,000-30,000 volts should be adopted, even should this entail a further transformation at some points where stations with different pressures have to be connected up.

At the above pressures it is possible to transmit outputs of more than 10,000 kw. through one cable. The cost of the feeder cable is reduced to about 2s. 6d. per kilometre per kilowatt transmitted, so that this part of the installation cost becomes of less importance for the short distance over which the energy has to be transmitted in cities.

A further means of reducing the cost of the network is found in the conversion of the entire system to a uniform alternating-current system, by laying ring mains and by interconnecting the various sections of the city.

Charges on capital.—The determination of the price for the current should be preceded by the fixing of the rate for capital charges, which must be regarded as the minimum for the prosperous development of the undertakings in question. In many instances the low rate of interest forms an obstacle when new capital is required; it prevents the concern from adopting progressive measures for improving the economy of the plant, and indirectly keeps the cost of the current unnecessarily high. On the other hand, it will be agreed that an undertaking which has to make use of public streets and thoroughfares, and is granted certain privileges by local authorities, is under an obligation to consider the interests of the general public in addition to its shareholders' interests.

The demands of the authorities, however, have unquestionably on many occasions exceeded reasonable limits, and by hampering the entire undertaking have impeded rather than assisted public interests. In my opinion, interest at 6-8 per cent on the value of the plant represents for undertakings of this kind the lowest limit which would ensure a favourable market for the company when it requires further capital. As regards the sinking fund and other reserves, an average figure of 3-4 per cent seems to be reasonable for power stations, sub-stations, and distribution system; for long-distance transmission lines and feeder cables in which the conducting material (copper) represents a high percentage of the total value, about 2 per cent may be sufficient. I have therefore based the following calculations upon uniform capital charges of 10 per cent for power stations, sub-stations, and distribution system, and 8 per cent for transmission lines and feeder cables, and I have called the current prices calculated from this basis "normal prices."

There are two ways of dealing with the control by the municipal authorities or by the public of the surplus profits above the agreed normal rates; namely, either by direct participation in such surplus amounts or by the reduction of the price at which the current is supplied under normal conditions. The latter form is doubtless the more appropriate, since consumers receive the benefit of the surplus direct, and reduced prices attract new consumers, so that both parties derive an advantage. Naturally a reduction in price should not be based upon the results of a single year's working.

Cost of operation.—The direct operating costs affecting the price of electricity chiefly consist of the following items: Coal, stores, wages, repairs, taxes, insurance, and general expenses such as wages, management, office costs, etc. The cost of the losses between the power station and the point of consumption must also be included here.

The costs of generation are directly dependent on the size of the power station, or on the size of the generating sets. Power stations with units of 20,000-kw. capacity consume only about three-quarters of the quantity of coal at full load compared with works in which modern 1,000-kw. sets are installed, and only half or even less of that consumed in older power stations with units of this size. The operating staff required depends chiefly upon the number of machines and not upon their size, this being more particularly the case in modern power stations in which human labour is replaced wherever possible by automatic machinery. Therefore labour costs are far more favourable in plants with large generating sets. The same applies to the sums required for repairs, stores, and general expenses.

The operating costs for the network are not directly dependent upon the size of the undertaking. By subdividing the distribution system in accordance with the best engineering practice, by simplifying the organization and by standardizing the plants, economies can be effected. Here again attention should be drawn to the superiority of the alternating-current systems over the mixed systems.

Transmission losses.—The transmission losses, which in the old plants amount to about 20 per cent of the energy generated, and thus represent from 10 to 15 per cent of the selling costs, can unquestionably be reduced to half this figure with the enlargement and standardization of the plant, this being more particularly the case in view of the fact that lower generating costs also reduce the cost of the losses.

Utilization of the plant.—A comparison between different undertakings and the prices at which they sell their current is only possible when the extent of their utilization is known.

By the term "utilization" I mean the ratio of the kw.-hours sold within a given period (usually taken as a year = 8,760 hours) to that number of kw.-hours which the plant would have been capable of generating if all the machines had been running constantly at full load during this period.

The utilization of the plant can thus be expressed by the following formula—

$$n = \frac{\text{kw.-hours sold per annum}}{\text{installed capacity of plant} \times 8760} = \frac{\text{average load sold}}{\text{installed capacity}}$$

This term has been in use for some years on the Continent. I have called it the "utility factor" (n) of the plant. The following particulars will show that the use of this factor affords valuable assistance in arithmetically following up the somewhat intricate relations between the cost of the current and the utilization of the plant.

In determining these functions it is necessary to ascertain the energy costs (or proportionate energy costs) both for the entire plant and parts of it when working permanently at full load, these values being characteristic and practically constant for each individual plant.

With regard to the capital charges (interest, dividends, sinking fund, etc.) this value (λ) is obtained by dividing

the annual interest by the product of the total plant capacity and the number of hours per year. If, for example, the capital charges are found to be k_2 shillings and the total capacity of the plant L kilowatts, the characteristic value for the capital charges is given by the formula—

$$A_2 = \frac{k_2}{L \times 8760} \text{ shillings per kw.-hour sold.}$$

As on the other hand the energy costs for capital charges with any desired utilization can be expressed by the formula—

$$K_2 = \frac{k_2}{\text{kw.-hours sold per annum}} \text{ shillings per kw.-hour sold,}$$

by dividing the above two formulæ we find that—

$$\frac{A_2}{K_2} = \frac{\text{kw.-hours sold per annum}}{L \times 8760} = n,$$

which is equal to the value defined above as the utility factor. Hence the relation between the utilization and the ratio of the capital charges to the energy costs is represented by the formula—

$$K_2 = \frac{1}{n} \times A_2 \text{ shillings per kw.-hour sold} \quad (1)$$

In a similar manner it can be shown how the direct-operating costs (coal, repairs, wages, etc.) depend on utilization. Here, however, the characteristic costs per kw.-hour (or full load) are partly independent of utilization. The relation between utilization and operating costs can then be found from the expression—

$$K_0 = \frac{1}{n} \times a_0 + b_0 \text{ shillings per kw.-hour sold} \quad (2)$$

It can be shown that the value a_0 represents those costs which would be entailed if the plant had to be kept ready for service without supplying useful energy; in other words a_0 are the no-load costs. The recognition of this fact enables the values a and b to be separated. Thus the proportion of the running costs to the selling price of energy can be determined for any utilization in accordance with Equation 2.

In determining the value a (no-load consumption) for the fuel of the power station, the time during which each set is run must be taken into account. It can be shown that this is done with sufficient accuracy for practical purposes by making the following modification of Equation 2:—

$$K_2 = \frac{n+1}{2n} \times a_0 + b_0 \text{ shillings per kw.-hour sold} \quad (3)$$

The transmission losses may be expressed by a similar formula on the assumption that the copper losses, which really vary as the square of the load, are proportional to the latter. This simplification appears to be permissible, since the cost of the losses only forms a small part of the total costs. The losses are thus found to be—

$$V_{\text{loss}} = \frac{1}{n} a_{\text{tw}} + b_{\text{tw}} \text{ kw.-hours per kw.-hour sold} \quad (4)$$

where a_{tw} = no-load losses (iron losses of converters, transformers, etc.), and b_{tw} = copper losses of transformers, cables, etc.

In order to obtain the cost of the losses, the above value must be multiplied by the price per kw.-hour generated (including profit and interest) found from the Equations 1 to 3.

The total selling cost per kw.-hour is thus found to be equal to the sum of—

Proportion of costs referred to the power station including capital charges.

Proportion of costs for the transmission and distribution losses including capital charges.

Proportion of costs for the operation of the transmission system including capital charges.

And they can be represented by a single equation—

$$K = \frac{1}{n} \times a + \frac{1}{n^2} \times a_1 + b \text{ shillings per kw.-hour sold} \quad (5)$$

which is called the costs characteristic for the entire plant. With this equation one can ascertain the average energy costs for the entire plant, and one can also graduate the prices payable for the various classes of consumption in correct steps as soon as their individual influence upon the utility factor is known.

Determination of the utility factor.—In view of the importance of the utility factor in connection with the selling price of the current, I now propose to discuss those points which determine the value of this factor.

One of the first points to be considered in this respect is the load factor, m , which is given for the entire plant by the ratio between the average load of the power station and the peak load, and can be expressed by the formula—

$$m = \frac{\text{kw.-hours generated per annum}}{\text{peak load} \times 8760} = \frac{\text{average load}}{\text{peak load}}.$$

This value is proportional to the utility factor.

Whereas in small plants irregularities in the consumption are perceptible in the power station, and the load factor in such stations may be affected by a single consumer, in large stations load fluctuations are equalized as the size of the plant increases. It is therefore possible to determine the form of the load curve, and therefore load factor, for large plants with sufficient accuracy from the outset, provided the general nature of the consumption is known. Leaving out heating and cooking, three principal classes of consumption remain—namely, power, traction, and lighting. Each of these classes possesses a special load curve, which is similar in all large cities and only varies for lighting according to the latitude. Whereas the power and traction load curves remain approximately constant throughout the whole year (with the exception of Sundays), the lighting load varies according to the season, so that both the average annual load and the maximum load in winter must be known in order to determine the load factor.

Such characteristic load curves for power, traction, and lighting are shown in Fig. 1. The maximum load in all three cases is assumed to be 100, the day of 24 hours being

divided into 100 parts, beginning at midnight. The load factors are—

Light	...	approx. 18 per cent (Sundays excluded)
Power	...	" 50 " " "
Traction	...	" 50 " " "

From these standard curves we can obtain the resultant load curve and also the resultant load factor "m" for any desired combination of lighting, power, and traction consumers.

As examples such combined load curves are set out in Figs. 2 and 3, the first showing a lighting and power curve, and the latter a lighting, power and traction curve. In order to include all conditions which have to be taken

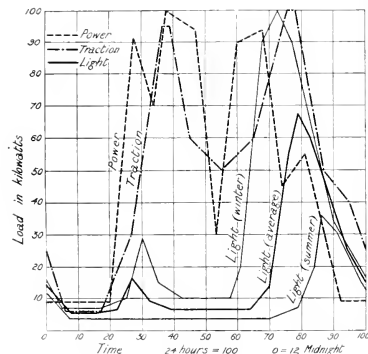

FIG. 1.—Daily load diagram of large power stations.

	Peak Load = 100,	Load factor
Power	...	= 50 %

Light:		
Summer	...	= 8 %
Winter	...	= 30 %
Average	...	= 18 %

into account and which are affected by various combinations of consumers and the degree of centralization, a further diagram, Fig. 4, has been drawn, based on the load curves given in Fig. 1. From this diagram the resultant load factor can be read off directly as soon as the percentages for power, traction, and lighting are known. If, for instance, the kw.-hours consumed comprise 20 per cent lighting, 12 per cent power, and 68 per cent traction (this approximately resembles the conditions in Chicago for 1911) then the resultant load factor lies at the intersecting point of the curve—

$$r_k = 12/20 = 0.6,$$

with the abscissa value—

$$r_s = 68/(12 + 20) = 2.13,$$

according to which a resultant load factor of 40 per cent for the above relationship may be expected, which approximately corresponds to the actual value obtained, namely 41 per cent.

This diagram demonstrates the important fact that by superimposing power and traction curves (top curve $r_k = \infty$) the load factor may be improved only by 2 to 3 per cent, while on the other hand by combining the power and traction supply with a lighting load of about 12 per cent, the resultant power factor is not materially decreased. Considering that in large cities 12 per cent of the total is not far from the actual requirements for

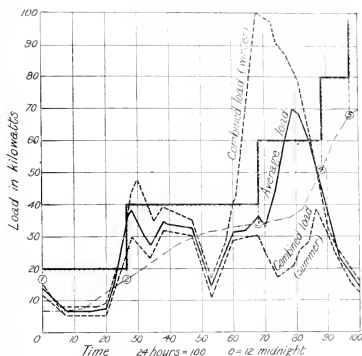

FIG. 2.—Daily load diagram or running time of machines.

Assumption: Light, 50 % of total output.

Power, 50 %

Traction, 50 %

Installed: 6 sets, output of each, 20 % of peak.

Stand-by: Permanent, 20 % of peak.

Overload, 4 hours, 35 %.

	Summer	Winter	Average

Consumption of fuel: $1.58 \alpha_s + b_s$, metric cal. per kw.-hour.

lighting, this means that it will be possible in future to generate (not to distribute) the current for lighting at practically the same price as for power and traction.

Next to the load factor, the efficiency of the network has to be taken into account in determining the utility factor. This efficiency is expressed by—

$$\eta = \frac{\text{kw.-hours sold}}{\text{kw.-hours at feeder busbars}}$$

This value is again in direct proportion to the utility factor.

So far as the selling price of the current is concerned, this means that the improvement of the distribution efficiency not only produces a saving in the cost of the

losses, but also (through the increase in the utility factor) causes a reduction of the remaining costs.

The third point is the amount of stand-by, the utility factor being inversely proportional to the capacity of the stand-by. Although it is difficult to state any rule for the percentage of stand-by to total plant, this percentage can be reduced with the increase in size of the total plant. This is mainly due to the fact that in the smaller stations the load curve is subject to more violent fluctuations. Therefore, in addition to stand-by for overhauling and

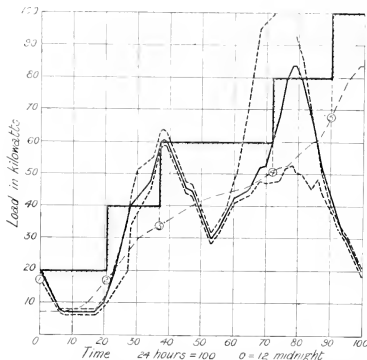

FIG. 3.—Daily load diagram for running time of machines.

Assumption: Light, 25% of total output.

Power, 25% of total output.

Traction, 50% of total output.

Installed $\frac{1}{2}$ sets, output of each, 20% of peak

Stand-by Permanent 20% of peak.

Overload 4 hours, 25%.

	Summer	Winter	Average
Load factor	33.8%	45.8%	39.5%
Utility factor	28.2%	38.2%	32.8%

Consumption of fuel $1.43 a_0 + b_0$ metric cal. per kw.-hours.

repairs, reserves are required to meet such variations in load. The stand-by factor is—

$$r = \frac{\text{installed output}}{\text{peak load in station}}$$

where the decimals indicate the percentage in spare plant.

The relation between utility factor, load factor, distribution efficiency, and stand-by is then given by the formula:—

$$u = m \times \eta \times \frac{1}{r} \quad (6)$$

By inserting this value in Equation 5 for the costs characteristic of the plant, the influence of any of the above factors upon the costs can be ascertained.

In view of the important effect on the utility factor resulting from a combination of various classes of con-

sumers, a few remarks should be made here bearing upon the practical possibility of such a combination.

In the early stage of electricity supply separate feeders and even separate generators were used for power and lighting. While in the meantime this practice has been abandoned, it is still usual in large cities at the present day to separate the supply for traction from that for lighting and power, or to provide special power stations and networks for traction. It must be pointed out that this method, which might be justified with a number of small plants, can only be condemned in the case of large power stations, since, as has been shown in Fig. 4, owing to the inferior utilization, this entails a waste of capital and a permanent disadvantage to consumers.

No disturbances are likely to arise from sudden current rushes caused by traction loads, as these are easily com-

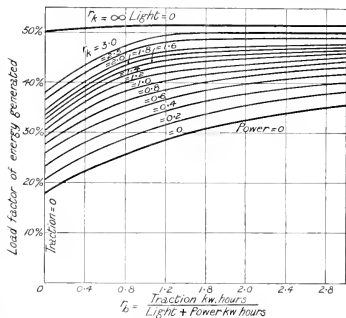

FIG. 4.—Load factor in large cities for varying ratio of light, power, and traction.

Based on lighting load factor = 18%

power load factor = 50%

traction load factor = 50%

$$r = \frac{\text{Power kw.-hours}}{\text{Light kw.-hours}}; r_b = \frac{\text{Traction kw.-hours}}{(\text{Light} + \text{Power}) \text{ kw.-hours}}$$

pensated for in large power stations. The statement made by supporters of separated systems that the traction demand is sufficiently heavy to justify a special plant is fundamentally wrong, since they overlook, first, that practically no traction station has yet reached the economical limits as regards size, and secondly, that the point of chief importance is not the reduction of costs for the traction demand, but of those for lighting and power supply, as shown above in connection with Fig. 4.

EXAMPLES TAKEN FROM EXISTING PLANTS.

It is now proposed to give a summary of the operating conditions in the Berlin, Chicago, and London plants, thus providing an opportunity for checking the foregoing statements by applying them to practical conditions.

For this purpose the material at disposal has been tabulated in such a manner that the items relating to the three plants can be directly compared with one another. The author has also succeeded, by making some assump-

tions, in determining the relation between working costs and utility factor, and has thus obtained the equation for the costs characteristic of all three plants. This conversion appeared to be necessary since the plants in question have a totally different kind of consumption, and therefore work with different utility factors. Any attempt to draw general conclusions on the advantages of one system over the other is bound to be misleading, unless this is done. Moreover, this analysis seemed to be the only means of obtaining a positive indication of the influence which the difference in centralization of the three plants exercises upon the working and energy costs.

COMPARISON OF WORKS STATISTICS IN BERLIN, CHICAGO, AND LONDON.

The comparative data have been summarized in Tables I to III of the Appendix.

The following remarks are made by way of explanation:—

The energy consumption per head of population cannot be compared directly from the figures given, since both in London and Berlin the energy is generated in special traction power stations, and in the case of Berlin that generated in block stations must also be included. Unfortunately, reliable data in this connection could not be secured; the figures for the years in question may be assumed, however, to be approximately as follows:—

Current consumption in kw.-hours per head of population:—

Chicago	310	kw.-hours
Berlin	170	"
London	110	"

These figures, although somewhat approximate, show that in the two latter cities the consumption should be capable of a considerable increase, even assuming Chicago to have reached the point of saturation, which, in the author's opinion, is not the case.

It is a striking fact that in London the generation of energy is split up amongst a large number of small stations, whereas Chicago stands pre-eminent as regards centralization.

The proportion of the average peak loads in the different stations is approximately as follows:—

London	1
Berlin	5
Chicago	10

In order to secure a basis of comparison for the real estate value of the plant, the author has in all cases subtracted the reserves, sinking funds, and all cash balances so far as they can be obtained from the balance sheets, with the exception of the working capital.

The installation cost per kilowatt is then found to be approximately as follows:—

Berlin	=	950	shillings per kilowatt installed
Chicago	=	1,200	" " " "
London	=	1,460	" " " "

It is noticeable that the cost per kilowatt of the Chicago plants is about 25 per cent higher than that of the Berlin plants, although the former are of nearly double the capacity. This may be attributed to a certain extent to the

cost incurred in buying up the competitive companies, the power stations of which have been put out of commission. This sum amounts to about 9-10 per cent of the total cost. The explanation of the difference which then remains between the Chicago and Berlin costs may possibly be sought in the different method of design, and in the more expensive living conditions prevailing in the United States. It is impossible, therefore, to draw any conclusions regarding cost per kilowatt.

A comparison is, however, possible between Berlin and London, where methods of design and living conditions differ less. From such comparison it will be seen that the total cost per kilowatt installed, with power stations of about 5,000 kw., is approximately 50 per cent greater than for power stations of about 25,000 kw.; this difference appears to be still greater, namely 80 to 90 per cent, when the costs of the power stations alone are compared. The ratio of the cost of the power station to that of the network (including meters) is also noteworthy; for Chicago and Berlin it is approximately 40.60, and for London 45.55. It can thus be seen that the cost of the power station decreases as the size of the plant increases. This matter will be referred to again further on.

With regard to the consumption, the three plants can be characterized as follows:—

Chicago: traction load predominating (approx. 70 per cent).

London: lighting load predominating (approx. 60 per cent).

Berlin: power, lighting, and traction loads in a more even ratio.

The Chicago load factors correspond to the values given in Fig. 4, because the conditions for a combined service of lighting, power, and traction appear to be fulfilled. Berlin remains somewhat behind these values in consequence of partial separation of different services and the influence of Sundays upon power consumption. London is considerably below the other two cities as regards the utilization of its plant, owing to its predominating lighting load. Fig. 4 shows that in London the load factor cannot be improved appreciably by centralization; what is necessary is to alter the nature of the consumption.

As reserve factors for power stations are altered with each extension, especially in the case of large units, it is advisable to take the average for a considerable number of years. Thus the figure of 11 per cent for Chicago seems too low, and the figure of 45 per cent for Berlin too high, while for London, where the largest machine unit is about 5,000 kw., the value of 61 per cent should be approximately correct. I consider the load factor should not largely influence the percentage of reserves. What affects the spares most is the size of the whole plant.

In view of such considerations the following reserve factors (*r*) appear to meet the normal requirements of large cities:—

With a maximum load on individual stations of 30,000 kw., $r = 1.25$.

With a maximum load on the separate stations of 15,000 kw., $r = 1.4$.

With a maximum load on the separate stations of 3,000 kw., $r = 1.6$.

It is assumed that each power station is equipped with at least one complete generating set as a stand-by.

Owing to the fact, expressed in Equation 6, that the utility factor depends not only on the load factor but also on the network efficiency and the reserve factor, the utility factors of the three plants differ to a greater extent

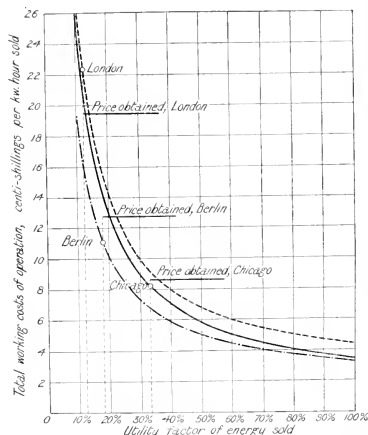

FIG. 5.—Total working costs per kw.-hour sold, including 10% for capital charges (interest, sinking fund, etc.).

	Berlin, 1911-12	Chicago, 1911	London, 1910-11
Capital per kw. installed ..	149,628.	1,200,368.	1,450,008.
Plant installed in kw. ...	137,000	221,700	208,400
Peak load in kw. ...	94,500	196,300	185,500
Energy sold in kw.-hours ...	$216\frac{1}{2} \times 10^6$	640×10^6	319.2×10^6
Load factor of energy generated	33.4%	41.0%	24.9%
Utility factor of energy sold ..	0.180	0.330	0.122
Overall efficiency			
= Energy sold			
= Energy in coal	9.7%	approx. 7.6%	approx. 5%

than would be expected from the nature of the consumption alone. The ratios are shown in round figures as follows:—

London.	Utility factor, 12% ; Load factor, 25%
Berlin.	" 18 " ; " 33 "
Chicago.	" 33 " ; " 41 "

These results, together with the remaining items in Tables I and II, enable their dependence upon the

utilization to be determined, and by means of the costs characteristic thus found the working conditions can be compared on an equal basis.

The results of these calculations are shown graphically in Figs. 5 to 8; Fig. 5 shows the total costs characteristic of the plant, while Figs. 6, 7, and 8 give the separate costs for generating, network losses, and network operation. The equations for these costs are put together in Table IV.

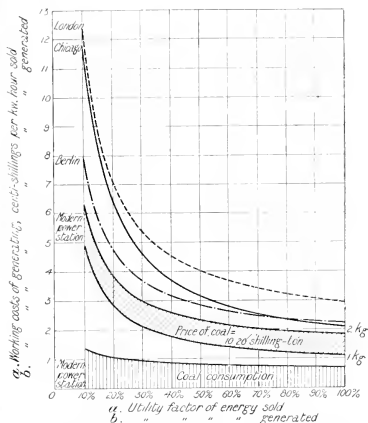

FIG. 6.—Working costs of power station as part of total costs (kw.-hours sold), including 10% for capital charges.

Comparison with costs of generating in large modern works.

Cost of coal: 10-20s. per ton.

Heat value of coal: 7,000 metric cal. per kg.

	Berlin, 1911-12	Chicago, 1911	London, 1910-11
Capital of power station per kw. installed ..	355,938.	477,108.	162,008.
Energy generated in kw.-hours ...	274×10^6	684×10^6	405×10^6
Load factor of energy generated	33.1%	41.0%	24.9%
Utility factor of energy generated	0.228	0.352	0.155
Utility factor of energy sold ...	0.180	0.330	0.122

The following particulars will explain the above calculations, and the assumptions which had to be made in certain instances where statistics were not available.

All costs include the capital charges, and in all three cases the normal rate of 10 per cent referred to above has been taken. Further, Items Nos. 38 and 39 in Table III, viz. current purchased and the special expenses for the Berlin and Chicago works, are omitted.

To allow the operating costs, Items 32 to 41, Table III, to be separated into power station and transmission costs,

it is assumed that the values in column 4, Table V, express this relation at full load and equal installation costs. These are then modified in columns 5 to 7 by taking into account the ratio of the installation costs for the power stations to those for the distribution system (Items 9 and 10, Table II). The items were further divided into costs which are dependent or not dependent upon utilization (values *a* and *b* of the costs characteristic equations) in accordance with the percentages shown in columns 8 and 9, Table V. Notwithstanding the uncertainty of these figures, it can be assumed that the final results are sufficiently in accordance with the actual values, since inaccurate assumptions may compensate one another to a certain extent, and the division of the main items, namely the capital cost and fuel, can be regarded as correct.

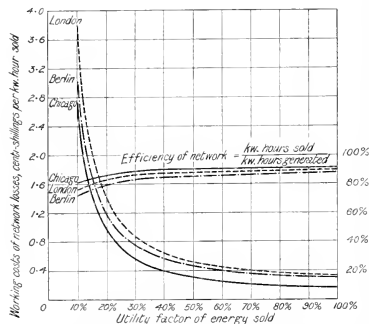

FIG. 7.—Working costs of network losses as part of total costs (kw.-hours sold), including 10% for capital charges.

	Berlin, 1911-12	Chicago, 1911	London, 1910-11
Energy sold in kw.-hours	$210 \cdot 3 \times 10^6$	$640 \cdot 0 \times 10^6$	$319 \cdot 2 \times 10^6$
Utility factor of energy sold	0.180	0.310	0.122

The actual utility factors, Item 23, Table III, are indicated in Fig. 5 by a circle. They therefore represent the "normal price" of the current, i.e. the price at which the works should earn a gross interest of 10 per cent on their capital, neglecting any special sums to be paid to the authorities.

The prices indicated in Fig. 5 by a horizontal line represent selling prices actually obtained by the works during the year in question (after deducting special expenses), and therefore permit a direct comparison with the normal value.

I may mention that in this address I have based my calculations upon the average selling prices throughout, and have ignored the division of the same into various classes of consumption, as this involves the question of tariffs, which does not come within the scope of the present subject.

RESULTS OF COMPARATIVE CALCULATIONS.

From these costs characteristics in Figs. 5 to 8 it will be seen that as regards total costs the Berlin works, notwithstanding their smaller power stations, work more economically than those in Chicago, while the costs of the London works are the least favourable. Nevertheless, the actual energy prices (based on equal utilization for all three plants) are approximately the same. The reason for this is that the selling price in London is about 13 per cent lower and in Berlin about the same percentage higher than the "normal" value.

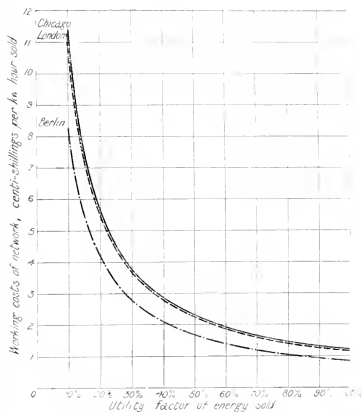

FIG. 8.—Working costs of network as part of total costs (kw.-hours sold), including 10% for capital charges, and excluding costs of electric losses.

	Berlin, 1911-12	Chicago, 1912	London, 1910-11
Capital of network per kw. installed	513 6/8	723 2/8	707 5/8
Energy sold in kw.-hours	$210 \cdot 3 \times 10^6$	$640 \cdot 0 \times 10^6$	$319 \cdot 2 \times 10^6$
Utility factor of energy sold	0.180	0.330	0.122

The relatively high working costs in Chicago, as compared with those in Berlin, are due in my opinion chiefly to the higher cost of the plant (Item 11, Table II) and the higher wages and salaries. Moreover, the Berlin plants show a decided superiority in fuel consumption, although this is counterbalanced by the appreciably higher prices for coal (see Items 24-26, Table III).

The importance of the utility factor for all three plants will be recognized from the form of the costs characteristic. The curves show that within the values for this factor of 10 to 30 per cent, the selling price can be reduced by more than 3 per cent for each advance of 1 per cent made in

utilization, without necessitating extensions or other alterations to the existing plant.

In order to gain some idea of the economy obtainable by the application of present-day experience, I have shown in Fig. 6 the characteristic for the generating costs in a large modern power station with machine units of 20,000 kw., based on coal prices between 10s. and 20s. per ton.

The lower vertical hatched section shows the coal consumption in a generating station of this kind, and simultaneously the costs for the same at a price of 10s. per ton. The area between the two hatched sections gives the

APPLICATION OF THE ABOVE DEDUCTIONS TO EXISTING PLANTS.

The foregoing outlines the chief points to be considered in large cities. We will now endeavour to find means for applying these principles to existing conditions.

In going over the results of the investigation of existing plants it will be noticed that the working costs for the network (Fig. 8) differ only slightly and form a relatively small part of the total working costs.

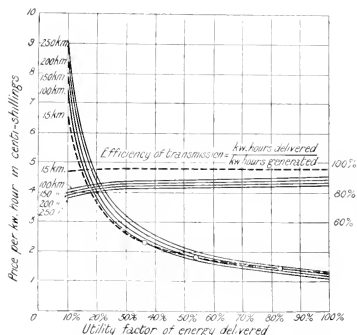

Fig. 9.—Comparison of total working costs between local and distant power stations with overhead line transmission.

Price per kw.-hour delivered at main feeding points of 20,000-volt ring system, and including capital charges of 10% on power stations and substations, and 8% on overhead line and cables.

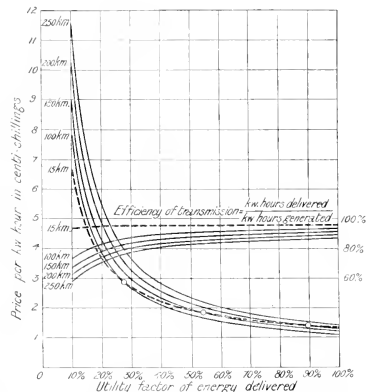

Fig. 10.—Comparison of total working costs between local and distant power stations with cable transmission.

Price per kw.-hour delivered at main feeding points of 20,000-volt ring system, and including capital charges of 10% on power stations and substations, and 8% on cables.

	Distant Power Station	Local Power Station
Distance from centre ...	100 250 km	Approx. 15 km
Transmission ...	Main = overhead at 120,000 volts Local = cable at 20,000 volts	Cable, 20,000 volts
Cost of coal ...	7s. per ton	10.5s. per ton
Heat value of coal ...	7,000 metric cal. per kg.	7,000 metric cal. per kg.

	Distant Power Station	Local Power Station
Distance from centre ...	100 250 km	Approx. 15 km.
Transmission ...	Main = cable at 120,000 volts Local = cable at 20,000 volts	Cable, 20,000 volts

Heat value of coal ...	7,000 metric cal. per kg.	7,000 metric cal. per kg.

generating costs, exclusive of coal but including 10 per cent capital charges. The comparison of the actual values obtained with those obtainable shows that with the same utility factor the generating costs in London, for example, could be reduced to less than one-half of what they are now.

A comparison on the same lines for the remaining operating costs (transmission) cannot very well be made owing to the divergency of conditions in the distribution systems. I nevertheless consider the superiority of Chicago (efficiency curves, Fig. 7) to confirm the opinion that a combination of the supply, and particularly a conversion to a pure alternating-current system, enables the cost of losses and distribution to be reduced considerably.

The saving to be expected here is small, because the greater part of the working costs consists of capital charges (see Table IV, Item 2).

A glance at the generating costs of the existing power stations (Fig. 6), and a comparison of the same with the values obtainable, distinctly shows that an effective way of improving the conditions would be to replace the existing power stations by large modern plants. This procedure, together with better utilization, would mean a saving of 30 per cent with a relatively small extra capital expenditure.

If, for example, all the existing power stations in London were shut down and large new stations took their place, a

saving could be effected of about 40 per cent on all working costs, at an increase of the total capital now invested of less than 20 per cent.

At this point a further possibility of reducing the working costs should be mentioned, which specially applies to large power stations and is dependent upon the site. This consists in a saving of coal costs by building the station in the immediate vicinity of coal-pits, and transmitting the energy through overhead lines or cables. It will be seen at once that this measure promises advantages wherever high coal freights prevail and where it is possible to use

extra capital expenditure. This means, according to the deductions arrived at above, that as great a proportion as possible of the existing stations with high working costs are to be replaced by a large modern power station, without any outlay on altering the existing distribution systems. Obviously these conditions are best fulfilled by those concerns which are to-day generating alternating current at the same periodicity.

From the statistics of the year 1910-11 it can be seen that during this time some 25 electricity works in and around London supplied alternating current at 50 periods,

FIG. 11.—Feeding system of the Berliner Elektrizitätswerke.

poor coal and obtain a good utilization of the transmission line.

Instead of firing the boilers with the coal direct, advantage may be taken under certain circumstances of the experience in the extraction of its valuable by-products such as nitrogen, tar, oils, etc.

NUMERICAL EXAMPLES.

I have worked out an example based on the conditions prevailing in London. Naturally I cannot claim perfection for this scheme, as some of the initial values have had to be assumed, but I believe that, notwithstanding this uncertainty, the results meet the case.

The method I followed is based on the desire to achieve a maximum improvement in working costs with a minimum

and represented altogether an installed capacity of 126,000 kw. Amongst these there are three concerns with more than 13,000 kw. capacity, totalling 46,000 kw.

These three stations, which are probably of a later date, show a relatively high economy, their immediate replacement is therefore unnecessary. The first step would then consist in providing a new power station having a capacity of 80,000 kw. to replace the 22 smaller stations, and in connecting their systems—which I assume to be distributed more or less uniformly—to a common network.

The interconnecting system would be laid out in a manner similar to the system adopted in Berlin for the recent extensions (see Fig. 11, 30,000-volt cable). Several ring mains would be run concentrically round the centre of the city, and the distance between rings would vary

according to the density of consumption. These ring mains would be duplicated in case of extensions and connected to one another by diagonal feeders.

In order to obtain an idea as regards the length and the cost of the cables, I have drawn in a system of this kind (Fig. 12) diagrammatically on a map of London, making due allowances for the increasing density of supply (shown by the closeness of the hatching) and the possibility of connecting up all the existing companies to the system. On the assumption that the total output of about 80,000 kw.

Twenty-five stations with an installed transformer capacity of $80,000 + 25\% = 100,000$ k.v.a. would be connected to the ring mains.

The new generating station is assumed to be situated within a distance of 15 km. (10 miles) from the centre of the city on a site of 50 ha. (130 acres).

Ten 20,000-volt cables, with the same dimensions and carrying capacity as the ring mains, would connect the latter to the power station. If the average length of the cable between the power station and the feeding points

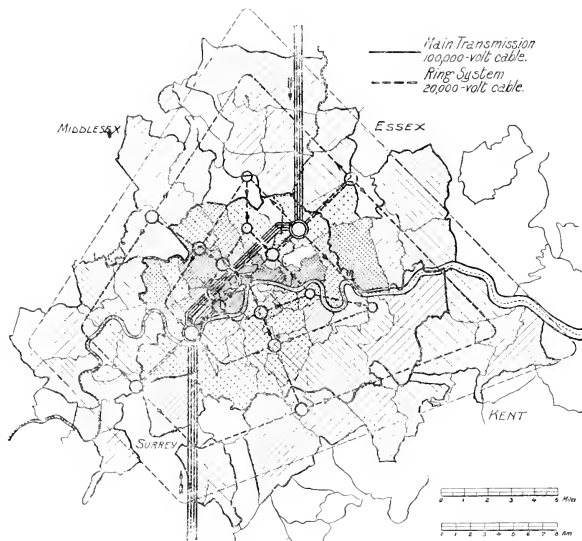

FIG. 12.—Assumed diagram of London Feeder System.

is to be distributed I consider that three ring mains, each consisting of one single three-phase cable, 3×150 sq. mm. (3×0.235 sq. in.), capable of transmitting 10,000 kw., should be sufficient. With this arrangement each of the stations belonging to the outer ring will be fed by at least two cables, while the cables laid diagonally provide for the necessary greater cable reserve in the interior of the city. I estimate that a ring system in accordance with the diagram shown in Fig. 12 will suffice for the distribution of 150,000 kw., showing that there is ample provision for further connections.

The total length of the cables would be approximately 250 km. (155 miles), allowing 15, 20, and 30 per cent for deviations from the straight line.

is assumed to be the same as the distance of the power station from the centre of the city, an additional allowance of 20 per cent being made for following streets, the total length of the cable would be 180 km. (110 miles).

The maximum losses in this cable would be approximately as follows:—

180 kw. dielectric losses;
3,240 kw. copper losses;

thus the characteristic for losses can be expressed approximately by—

$$\frac{1}{H} \approx 0.0023 + 0.0428 \text{ kw.-hours per kw.-hour supplied.}$$

On the above assumptions the costs work out as follows—

A. Estimate—

1. Power station 83,000 kw., including transformers, switch-house and auxiliary buildings, @ 170s. per kw. Extra for site, pile foundations, pumping plants, labour, etc., @ 40s. per kw.	Shillings.
Total	17,430,000
2. Feeder cables 180 km. 20,000-volt 3×150 sq. mm. section, including laying, @ 27,800s. per km.	
Total	5,000,000
3. Ring cables, 250 km., 20,000 volt 3×150 sq. mm. section, including laying, @ 31,000s. per km.	
Total	7,750,000
4. Sub-stations: 25 with stationary transformers. Total capacity, 100,000 k.v.a., allowing for the partial use of existing building and sites, @ 40s. per k.v.a.	
Total	4,000,000
Total cost	34,180,000
or 427.25s. per kw.	

B. Operating costs for the new plants.—

Capital charges—

Power station and sub-station	10 per cent
Cable	8 „
Coal—	
Price per ton	10s. 6d.
Caloric value per kg. 7,000 cal. (12,600 B.Th.U. per lb.)	
Utility factor for all plants based on full load 80,000 kw.	

Operating costs, including capital charges, are then calculated as follows:—

- Power station $K = \frac{1}{n_{es}} \times 0.479 + 0.733$ centi-shillings per kw.-hour generated.
- Feeder cables,
 - Losses $V = \frac{1}{n_{es}} \times 0.0023 + 0.00428$ kw.-hours per kw.-hour supplied.
 - Cost of losses $K_v = V \times K$ centi-shillings per kw.-hour supplied.
 - Operating costs $K_{sp} = \frac{1}{n_{es}} \times 0.074$ centi-shillings per kw.-hour supplied.
- Ring mains and transformer stations $K_r = \frac{1}{n_{es}} \times 0.185$ centi-shillings per kw.-hour supplied.
- Total costs $K = K_s + K_v + K_p + K_r$ centi-shillings per kw.-hour supplied.

The total costs, Item B 4, cover the energy supplied on the low-tension side of the 20,000-volt step-down sub-stations, and can therefore be compared with the costs per kilowatt-hour generated in the existing power stations (see Table IV, Equation 1).

C. Operating costs of the old plants.—These are composed of—

- Capital charges on the real value of the 25 power stations with a total output of 126,000 kw., the amount of which is assessed at 662s. per kilowatt in accordance with Item No. 9, Table II, and
- The direct operating costs for the three old stations with installed capacity exceeding 10,000 kw. kept in commission. As it was assumed that the economy of these three stations is higher than the general average economy of all London works, I have assumed the cost characteristics follow a curve lying between the average London costs (see Table IV, Item 4) and those of the new power station (Item B 1), deducting capital charges, which are included in the first part of this section.

I have further assumed that, in view of the high proportion of the lighting load, the new power station can deal with the entire supply without assistance during a considerable part of the year, and that the three old power stations need be operated for not more than an average of 8 months in the year.

The utility factors are to be based as regards capital charges on the existing plant of 126,000 kw., and as regards operating costs on the capacity installed in the three old stations of 46,000 kw.

The operating costs of the old plant are then found to be as follows:—

- Capital charges as hitherto, about 8 per cent on 83,412,000s.—

$$K_s = \frac{1}{n_{25}} \times 0.605 \text{ centi-shillings per kw.-hour supplied.}$$

- Operating costs for the three old power stations, exclusive of capital charges—

$$K_v = \frac{1}{n_{46}} \times 0.387 + 1.340 \text{ centi-shillings per kw.-hour supplied.}$$

- Total costs—

$$K = K_s + K_v \text{ centi-shillings per kw.-hour supplied.}$$

The figures obtained from the comparative calculations made on the foregoing basis are combined in Table VI. The results of these calculations may be summarized in the following statement. The plan proposed permits payment of interest and amortization of the old capital in the same manner as hitherto, and leaves a reasonable sum for capital charges on the new capital and a surplus of 5,200,000s. This profit is secured without making any alterations in the existing distribution system. The increase from 135,000,000 kw.-hours to 172,000,000 kw.-hours would meet the natural increase in the consumption during the construction period.

We will now consider the effect of the above scheme on concerns supplying continuous current. According to the statistics of 1910-11, there are 29 companies under this heading with an installed capacity of 116,000 kw. If the largest of these stations with outputs of 10,000 kw. might at first remain in commission (there are three of these works with a total output of 54,000 kw.), the others would be

shut down, and as the ring mains have still an ample reserve, the only alteration would be the installation of 62,000 kw. of converters and transformers, the laying of about 7 additional feeder cables, and the extension of the new power station by 3 generating sets. This alteration could be carried out at a cost of about 310s. per kilowatt installed. After this alteration about 80 per cent of the existing plant will have been combined and transformed into an efficient supply system. The conversion of the remaining concerns with non-standard systems would probably no longer offer great difficulties.

COMPARISON: DISTANT AND LOCAL POWER STATIONS.

The foregoing calculations were carried out on the assumption that a new power station would be erected in the vicinity of the city supply area. The question that remains to be examined is whether greater advantages could be obtained by erecting the new power station at coal-mines and transmitting the energy to the city by long-distance transmission lines. A general investigation does not appear to indicate promising results. A scheme of this kind is dependent upon a number of factors which vary according to the prevailing conditions. I may mention in this respect that apart from coal freight and the distance of the mines, the price and quality of the coal and the economy of the plant influence the results.

In order to investigate the matter more closely I was obliged to take certain figures as constants and to confine myself to a consideration of the following points:—

- Distance of the mines from the city.
- Utility factor.
- Transmission system (overhead line or cable).

With regard to the constants, I have taken normal values adapted as far as possible to London conditions.

Basis for the comparison of local and distant power stations.

Difference in price of coal delivered free at bunkers	3s. 6d. per ton
Price of coal delivered free at bunkers, distant power station	7s. per ton
Caloric value of the coal	7,000 cal./kg. (12,600 B.Th.U. per lb.)

Economy of power station corresponding to the characteristic for modern plants, Fig. 6.

Cost of power station—	
At the mine	170s. per kw.
Near the city	210s. "
Max. output at end of line	80,000 kw.

The last value corresponds to the power-station output in the previous example. Moreover, there will be no essential alterations in the results of the comparison if, in place of 80,000 kw., 2 or 3 times this value is taken, as this

merely entails an alteration of the absolute value, while the relative figures which are of importance for the comparison remain approximately the same.

I consider the extra cost of 40s. per kw. for the local power station justified in consequence of the appreciably higher land values, the expensive pile foundations that may be required on the Thames, and higher wages, salaries, etc.

For the long-distance transmission I have selected three-phase current at 50 cycles, with a line pressure of 100,000 volts, both for overhead and cable transmission.

My reason for suggesting such a high working voltage for cable transmission requires some explanation. As the neutrals of the system would be permanently earthed, the pressure between earth and conductors would be 60,000 volts. Single-core lead-covered cables laid direct in the ground with mechanical protection would be employed. Cable manufacture has made sufficient progress for the use of such voltages. Apart from manufacture, the electrical phenomena have also been investigated, and the accompanying difficulties can be overcome. It should also be borne in mind that with such high pressures and the attendant high strain on the insulation, the idea of employing cables cannot be entertained unless the energy to be transmitted is very considerable and the sections of the cable become large in consequence. The recent development towards large power stations and long-distance transmission has therefore advanced conditions in favour of high-tension cables, so that for installations of this kind under certain circumstances as are encountered in large cities, cables appear to be equally satisfactory or even superior to overhead transmission lines.

In preparing comparative calculations I have assumed a smaller average distance between masts than is advisable under ordinary circumstances. In addition I would propose purchasing a strip of land 15 metres wide for each line of masts at an average price of 600s. per ha. (= 2.47 acres).

It is necessary to provide two rows of masts to allow for repairs, whereas with single-phase cables one cable per circuit suffices as a reserve, provided it can be put into commission without interrupting the supply.

Overhead transmission lines cannot be continued as far as the feeding points near the centre of the city, and the main step-down station must therefore be placed on the outskirts of the city unless 100,000-volt cables are used for taking the energy into the city. In the comparative calculations I have taken the first suggestion, and an amount must therefore be included in the estimate for a feeder cable equal to that for the local power station under Item 2 on page 135.

The comparison includes the plant up to the feeding points of the 20,000-volt ring mains (see Fig. 12), as from this point the systems and methods of working are the same for all cases. The distances from the mines are taken as 100 km., 150 km., 200 km., and 250 km. respectively. The costs then work out approximately as follows:—

A. Local power station (see page 135).

1. Power station: 83,000 kw.	17,430,000s.
2. Feeder cable: 20,000-volt	5,000,000s.
	22,430,000s.

B. DISTANT POWER STATION WITH OVERHEAD TRANSMISSION.

Installation cost in shillings.

Distance	Power Station	Overhead Transmission	Main Step-down Station	Feeder Cable	Total
100 km.	15,040,000	4,700,000	1,700,000	5,000,000	27,040,000
150 „	15,980,000	7,050,000	1,700,000	5,000,000	29,730,000
200 „	16,150,000	9,400,000	1,700,000	5,000,000	32,250,000
250 „	16,320,000	11,750,000	1,700,000	5,000,000	34,770,000

DISTANT POWER STATION WITH CABLE TRANSMISSION.

Installation cost in shillings.

Distance	Power Station	Cable Transmission	Main Step-down Station	Total
100 km.	14,620,000	10,470,000	1,700,000	26,790,000
150 „	14,950,000	15,915,000	1,700,000	32,575,000
200 „	15,300,000	21,580,000	1,700,000	38,580,000
250 „	15,640,000	27,400,000	1,700,000	44,740,000

The results of the comparison for all the foregoing cases have been tabulated in Figs. 9 and 10. Fig. 9 shows the comparison between a local power station and a distant power station with overhead transmission, and Fig. 10 the same with cable transmission, the values including to per cent for the capital charges on the power station and sub-stations, and 8 per cent for the overhead transmission line and cable. These calculations prove that the working costs with cable transmission are higher than with overhead transmission at low utility factors, and that with the utilization of about 50 per cent they are practically equal. The curves further show that under the assumptions made, the local station can be operated more cheaply than the distant station. The operating costs of the former, however, approach those of the distant station, and from a utility factor of 30 per cent upwards exceed them at 100, 150, 200, and 250 km. transmission distances.

CONCLUDING REMARKS.

The comparison has shown that under certain conditions, namely with coal freight at 3s. 6d. per ton and with a normal utility factor, it would be cheaper to operate a power station situated near the city than one at the coal-mines. I do not, however, look upon the difference as sufficient to decide so important a matter as the locality of the power station. There are other considerations of a more general nature that have a considerable bearing on the point at issue.

In this connection it follows from the arguments given that by reducing the operation of the six existing stations more than I have assumed, and using them for peak loads or as a stand-by only, one can obtain a higher economy and reduce the total costs for the power station at the mines.

A variable item in the calculations is coal freight. I have taken 3s. 6d. per ton for freight; it seems unlikely that the freight rates will remain constant for a number of years.

A question which is also of great importance is the possibility of using low-grade fuel at the mine, viz. fuel which it would not be worth while to transport to a power station near the city. One might be able to secure protection against a rise in the price of this fuel by the acquisition of a coal-mine.

The towns and districts surrounding the coal-mine station could conveniently be reached from the same and could thus enjoy the benefits of a cheap and reliable supply.

A much-discussed subject is the extraction of by-products from coal; and it would be of interest to examine under what conditions the processes now in use could be applied in connection with the very large amount of coal that would be required.

These are all considerations that call for a careful scrutiny before deciding on the principles to be followed in connection with electricity supply of large cities.

36	Rent, taxes, insurance, etc.	0.348 "	0.605 "	1.482 "
37	General expenses... ..	0.840 "	0.836 "	1.399 "
38	Current purchased	—	0.167 "	—
39	Municipal participation	3.067 "	0.271 "	—
40	Total expenses	8.134 "	4.514 "	8.720 "
41	Profit (gross)... ..	7.722 "	4.530 "	10.810 "

The conversion to kw.-hours sold includes the number of kw.-hours purchased; therefore the actual value is approximately 4.5 per cent higher.

TABLE IV.

Equations for operating costs of existing plants, n = Utility factor.

Portion of Plant	Working Costs including Capital Charges per kw.-hour sold, in Cent-shillings		
	Berlin, 1911-12	Chicago, 1911	London, 1910-11
1. Power station (excl. transmission losses)— K_{en}	$\frac{1}{n} \times 0.635 + 1.007$	$\frac{1}{n} \times 1.071 + 1.036$	$\frac{1}{n} \times 1.034 + 1.046$
2. Transmission system— K_{ent}	$\frac{1}{n} \times 0.821 + 0.033$	$\frac{1}{n} \times 1.114 + 0.057$	$\frac{1}{n} \times 1.111 + 0.026$
3. Transmission losses—			
(a) $V_{kw} = \text{kw.-hours}$	$\frac{1}{n} \times 0.028 + 0.111$	$\frac{1}{n} \times 0.017 + 0.068$	$\frac{1}{n} \times 0.022 + 0.088$
(b) Cost	$V_{kw} \times K_{entn}$	$V_{kw} \times K_{entn}$	$V_{kw} \times K_{entn}$

TABLE V.

Assumptions made for division of the working costs.

Division of Working Costs per Kw.-hour sold										
Working costs			Power station (incl. transmission losses) Network costs				Dependent upon Utility Factor			
Position	Installation costs		Power station Network		Working costs		Power station Network		Dependent upon Utility Factor	
	See Items 9, 10 Table II				Without		With Reference to Installation Costs			
	Berlin	Chicago	London		Berlin	Chicago	London		Dependent	Independent

DISCUSSION BEFORE THE INSTITUTION ON 4TH DECEMBER, 1913.

Sneli.

Mr. J. F. C. SNEEL: I propose only to deal with a few of what appear to me to be the most salient points in Dr. Klingenberg's address, and not to go into such details as utility factor or his other useful equations. I feel a very full sense of responsibility in speaking upon a question of this sort because it is very obvious that Dr. Klingenberg's address is directed particularly to the supply of electricity in London. As that is a matter with which I have had a good deal to do during the last 6 or 7 years I feel, as I say, a full sense of responsibility, a sense of responsibility to the London County Council, and also to those who are at present advising the Council, in that I do not wish to overstep the limits of proper discussion while this matter is still *sub judice*. I think we shall agree with Dr. Klingenberg where he says that if we were dealing afresh with the electricity supply of any great city, London or elsewhere, any engineer to-day would suggest one or more large three-phase stations generating at perhaps a moderate pressure, stepping up to a higher pressure for transmission, and stepping down at strategic points to three-wire or four-wire low-tension distribution for general supply, *i.e.* lighting and power, and of course converting for traction supply. Nobody will to-day disagree with such a statement as that, but in London we have very peculiar difficulties. In the first place the County Council have the power to purchase the present companies in the year 1931 on the terms of the 1888 Act, which up to the present are undefined; by that I mean that they have not been fought out in the way that Section 43 of the 1870 Tramways Act has been fought out, and nobody knows what the exact terms of purchase will be. Under those conditions it is obvious that the companies must have difficulty in raising money for extensions, and this difficulty will increase the nearer we approach to 1931, so long as the present conditions of purchase remain unaltered.

I should like to refer to one or two axioms which I think most power-station engineers will accept. One is this, and it has been impressed upon me very clearly in dealing with a number of metropolitan undertakings during the last 4 or 5 years, if we consider a station of moderate size the cost of extending that station to-day is not very high, and the cost of producing energy from the new plant is really very small indeed, and it is a very difficult matter for a bulk supply, no matter how favourably placed, to deliver electrical energy within certain limits at a cheaper rate than it could be generated from that extended plant. It must be remembered that I am now referring solely to the additional plant. In the second place, everybody will agree that if there were virgin ground where there was no local supply of electricity and a proper bulk supply was available, no engineer would dream of erecting a small local station instead of purchasing energy in bulk and distributing it accordingly. But in dealing with the supply of energy in bulk, as I think I pointed out in 1904, we must bear in mind that the reduced cost of energy due to the larger plant and probable higher load factor, may be neutralized by the cost of the transmission mains and by the losses in conversion from alternating to continuous current. There are those three points therefore which have really to be kept in mind.

We have heard a good deal about the backwardness of

electricity supply in England. Mr. Mordey dealt with that in his Presidential Address,* and Dr. Klingenberg has referred at length to the supply in the city of Chicago. Now let us see what is actually the position there. The capital invested is roughly £15½ millions, or £69 per kilowatt. The average cost throughout Greater London is £80 per kilowatt, but in Chicago the greater proportion of the supply is given for traction; thus of the total number of units sold, namely about 712 millions, no less than 484 million units are sold for traction, or, as called in America, transportation systems. Then 480 million units are sold at an average cost of 0.405d. at a load factor of 50 per cent. If I deduct from the total the number of units sold for traction, I find that there is a remainder of 229 million units for lighting and power, from which a revenue of approximately £2½ millions was obtained, the average price being 2.34d. Dr. Klingenberg actually mentioned that figure, or practically that figure. The average price in London is 2.4d.; so that if we compare the average cost of electric light and power in Chicago, the "Electrical City" as it is called, with the cost of lighting and power in London, there is not much difference. Let me be fair; I appreciate that the conditions of living are different in America from what they are in London; the cost of living is higher, but I doubt if there is any serious difference in the cost of producing electrical energy. Omitting the traction supply, the number of units sold per head of population in Chicago was 105 in the year 1912, compared with 70 in Greater London, again excluding traction. In the district of Marylebone, which has the largest output *per capita* at the present moment, the consumption of electrical energy is 100 units *per capita*; so that there is not a great deal of difference between Marylebone and Chicago in regard to the sale of electrical energy for lighting and power. Indeed, in Marylebone I understand that the greater part of the supply is for lighting and heating, together with a certain amount for cooking. If, again, I take one of the large power companies in New York, I find that with plant installed of 217,000 kw. capacity the capital expended is £113. The average price per unit is 3½d.—that figure, however, includes the supply of a certain number of free lamps—and the number of units *per capita* is 110. Similarly in Boston the number of units is 110 *per capita*. So that there is not a great deal of difference, when we compare like with like, between the sales of electrical energy in Chicago, Boston, New York, or London. The whole point lies, of course, in the fact that the transportation systems in London are not developed to their full extent, and therein, I think, lies to a large extent the key to the situation. What is the position in London? The output at the present moment is 460 million units, the number of kilowatts installed is 320,000, and the actual cost of land, buildings, and plant is roughly £41 per kilowatt—that is approximately one-half of the total capital invested in the whole of the undertakings. But here is an important point: the total of all the maximum demands in London last year was 203,000 kw., and the capacity of the plant installed was, as I said, 320,000 kw., leaving no less than 117,000 kw. in reserve,

Mr. Sneli.

* *Journal I.E.E.*, vol. 42, p. 10, 1909.

or practically 36 per cent. That of course is one of the direct results, as Dr. Klingenberg pointed out, of having the plant distributed over a large number of comparatively small stations. The utility factor was low. The actual capital investment in the 64 stations—that is investment in land, buildings, and plant—is approximately £134 millions. Without going into details, I may state that the cost of replacing that plant by two bulk stations at a moderate distance from London, with the necessary transmission mains and converting or transforming apparatus which would be required in the existing stations, would be approximately £6,000,000, so that there would be an actual saving in capital of £7,000,000 if we had not got the 64 existing stations and could begin anew with two bulk stations. What would be the saving in the working? I have calculated this out with care, and find that the cost would be somewhere in the neighbourhood of £1,000,000 per annum, that is 0.38d. per unit delivered to the consumers, or a reduction on the present average charges in London of 26 per cent. Of course that would be a splendid thing if we could only do it; but, unfortunately, that is not the position. We cannot ignore the existing stations, so what we have to consider, as it seems to me, is: What is the best compromise that can be arranged? I know I shall be criticized; but my own personal belief is that the psychological moment (which might have occurred 8 or 9 years ago) for a bulk supply of electricity to the whole of the traction undertakings of London has passed away. There are some suburban lines, of course, still unelectrified, and no doubt if proper terms were offered them they might, as in the case of the London, Brighton, and South Coast Railway, purchase their energy in bulk; but some of the great railways, those that have the best suburban services, like the London and South-Western Railway, the London and North-Western Railway, the Great Northern Railway, and the Great Western Railway, already have power stations, or soon will have power stations, of their own. They have started to build them. I think that has put back, at any rate for a great many years, the chances of any great amalgamated supply selling energy to those suburban lines. That makes a great difference to the whole situation, as it seems to me. If that may be granted, we, I think, come to the point: What can we do to wipe out some of this large number of small stations and replace them by stations which will supply energy at a cheaper rate? I myself believe, from a fairly intimate knowledge of all those stations, that there are some 8 of them which should be retained. It would pay, moreover, to extend these stations because of their geographical positions and certain facilities which they enjoy. I believe, too, that it would be possible to use those 8 power stations not only to supply the areas which they are permitted by Parliament to supply, but also to go beyond those areas. Let me call those the first-class stations. Secondly, there are about 10 stations it would pay to extend to a limited degree—limited, I mean, either by the facilities which they can obtain for condensing purposes, or the limitations of a circumscribed site or of coaling. The other stations, which number about 36, will, in my opinion, be gradually superseded. It will not come at once; it cannot come at once, except in a few places, because of the money which has been invested in those power stations.

Mixed up with this problem of the present is the problem

of the future. Let me leave aside for the moment, for the reasons which I have stated briefly, the question of a big transportation load; and let us consider what is likely to be the growth during, say, the next 10 years. Of course it will be said that it is a very hazardous guess—I admit that it is—but let us assume, and it is somewhat borne out by statistics for the last 2 or 3 years, that in the next 10 years there may be an increase in capacity of 150,000 kw. What will be done with it? All engineers will agree that it would be unwise that 150,000 kw. should be spread in small units over 64 stations. I do not suppose that will be done. I think, therefore, if facilities could be given at once for the starting of a well-placed bulk station, that plant can be installed in that bulk station to meet this gradual growth. Having got that station started, and possibly a little later a second station, we should be in a position gradually to shut down the 36 small stations which I mentioned. Let me summarize for a moment at this point. I say that there are existing capital commitments which cannot be overlooked, and that only a gradual replacement of the existing plant can take place. I believe the best solution at the present moment, and I say it unhesitatingly, is that the generation of energy in London should be in the hands of one authority, and that this authority should supply energy wholesale to existing authorized distributors, and that these authorized distributors should continue to exist as distributors, and manage the business in their own local areas—not only up to 1931, but afterwards.

Dr. Klingenberg next goes on to discuss the relative merits of stations placed close to London and stations situated, as he terms it, at the pit's mouth. The nearest coalfields we have are the Kent, partially developed, 50 miles in a straight line from London, and the Nottingham and Western coalfields, about 100 miles from London. He takes as his comparative figures £10.5 per kilowatt for the stations near London, and £8.5 per kilowatt for the stations situated at a distance. If he knew England and those districts round the coal-pits fairly well, I think he would naturally ask himself what is he going to do, at any rate in the Midland coalfields, for a supply of condensing water, because it seems to me for high turbine efficiencies a good supply of circulating water is as necessary as a cheap supply of coal. First of all, I would assert that a very marked economy would have to be shown to Parliament and the other authorities interested before they would be content for the supply of London to be dependent upon a very high-pressure supply obtained at so great a distance from London, with the undoubted—I do not wish to magnify them—extra risks which such a system must necessarily entail. I think everybody must agree that the further we go afield and the higher the pressure the greater must be the risk. Anyway, let me put it fairly at that. Then when in America and other places they take energy from a very distant station they install batteries to a great extent in the cities. I do not think Dr. Klingenberg has taken batteries into consideration. They have a fairly high initial cost, and a moderate cost for maintenance. But looking at some of his estimates—necessarily I have had to do it rather quickly—I must confess that I think some of his figures are considerably open to criticism. For instance, he talks about the cost of transmission lines, two lines being taken over a strip of land 15 metres wide for a distance of 62 kilometres, or 100, or

Mr. Snell.

Mr. Snelc whatever it is, and says that the price is 600s. per hectare. Now a hectare is $2\frac{1}{2}$ acres. Does he think in England he will get land at £12 an acre? It ought certainly to be multiplied by at least 7 or 10. I have increased the figure of £485,000 for the two lines to £600,000. It is not a very large alteration, but the total cost of the distant station with 92,000 kw. installed, that is to say capable of delivering 80,000 kw., would be approximately £1,500,000, or £183 per kilowatt installed. The local station, taking Dr. Klingenberg's own figures, would be £871,000, or £41 per effective kilowatt. What saving do we get? He assumes a saving in carriage of 3s. 6d. per ton of coal. If the station had an annual load factor of 35 per cent, which I think is a reasonable figure to take, the coal consumption would be about 250,000 tons per annum, and the annual saving therefore would be about £44,000. That is, I think, the maximum saving which would be obtained as between stations placed at a distance of 50 or 100 miles from London, and a station at the outskirts of London. There might be some saving in wages, but it would be very slight. There might be some saving in rating, but I think that the assessment on the transmission lines would neutralize the reduction in the assessment on the power station. I cannot see any other saving. I will confine myself to this. There would be a saving in coal of £44,000 a year; but Dr. Klingenberg has had to spend practically another £500,000 and has to pay the capital charges upon that. Taking it on, I think, a very fair basis, taking, for instance, the life of transmission towers at 40 years, I estimate that the capital charges alone would absorb £12,000 per annum; i.e. there is still a saving of £32,000. Then there is the cost of patrolling and maintaining the lines, painting the towers, and certain repairs; it may be said this is not a very big figure, but still it all costs money, and I think when we come to take a line in England of 100 or 50 miles it will be found that that item accounts for a few thousand pounds a year. Putting it briefly, I come to this conclusion, that taking a station 50 miles away we might possibly obtain a saving of £20,000 per annum. What would it mean? The station would be capable of generating 200 million units per annum—it probably would not do so much—and the revenue would be approximately—I do not mean to say the cost of energy sold to the consumer, but the revenue as a power station—£275,000 a year. We thus get a saving on paper of £20,000 a year on a revenue of £275,000, whilst taking the risks of a station supplying energy at very high pressure over a distance of 50 or 100 miles. I confess I do not believe that would commend itself to the authorities. I do not know that it will commend itself as an engineering adventure to engineers. Finally, I may say this, and I am not speaking at random; four or five years ago Mr. Fell, Mr. Rider, myself, and others, had to go with great care, and with as much exactitude as we could muster, into the relative cost of a station situated 40 or 50 miles away from London and a station situated only 10 miles away, and on estimates carefully confirmed we came to the deliberate conclusion that the home station, a station within 10 or 15 miles of London, was the cheaper proposition and the better engineering proposition.

In conclusion let me just say this. What we ought to be concerned about as engineers and as an Institution is this. We do not want to see the development of elec-

tricity in London delayed by inept legislation or by the play of political parties, or by its being made the sport of financial groups. What we do want to see is that there is freedom given for the proper and careful development of the supply in this great city. Mr. Insull is reported in the *Times* only a day or two ago, in his speech to the Investment Bankers' Association of America, to have said that the greatest item of expense is not the cost of coal or of labour, but of money, and I think most of us will agree that that is true. Therefore I say that what is wanted is an accelerated development, a supply consistent with a proper regard for existing conditions and future growth, and I believe that the best solution is the gathering together of all the generating stations in Greater London into the hands of one constituted authority now and not 18 years hence; and that that constituted authority should supply energy wholesale to the existing distributors, leaving the existing distributors, whether company or municipal, the enjoyment of their present areas, the right to distribute energy, and the right to manage their own local business.

Dr. S. Z. DE FERRANTI: The greatest compliment that we could show Dr. Klingenberg would be, rather than our applause, a full, complete, and satisfactory discussion on his address; but I should like to explain for those who do not know it, lest this discussion might be considered representative of English electrical engineers, that many if not most of the engineers whom we should like best to have heard are precluded from speaking upon this subject by the position of electrical affairs in London at the present moment. Now from my point of view, if I were coming to London and looking at this electrical supply for the first time, I am afraid I should be led to think it was about the maddest arrangement that it was possible to conceive in the way of electricity supply, and no doubt many engineers and many business men in other countries think what a wonderful people we must be to have conceived such a terrible state of affairs for our capital city. Well, now, the trouble is not electrical, and it is not engineering; the problem originated long ago in the desire to make a huge experiment, and in my opinion resulted unsatisfactorily from the preponderance of the politician over the engineer and the business man. The primary object was to benefit the public, and usually when legislation tries particularly hard to benefit the public, the public is nowhere except in the way of paying. Now gasworks were very successful in the early days in this country, and this success has continued. Years ago when electricity was just starting on its business career for what I should call the heavy side, that is to say apart from telegraphy, there was a great feeling that everything of the nature of public supply should be carried on in the interests of the community. In other words it was desired to make municipal trading of it, and electricity being the newest thing, the most promising thing, and with the least strength to support and defend itself, was taken hold of by the politicians in the name of the public, and London's present system of electricity supply has been the result. There was no consideration of what were the best positions for stations and the best areas of supply, but the only guiding idea was that each parish or local authority should have its own small electricity supply all to itself. That is how the present state of affairs originated. Where the municipality did not get this power and a company came in, the trouble was further

anti-aggravated by the fact of there being two companies, not who might work sensibly together, but who were forced to compete and offer two kinds of electricity supply, namely, continuous and alternating current. Thus Dr. Klingenberg and engineers in other parts of the world must not imagine that London is part of an electrical design; they must know that it is part of a bad system in the first instance, but not of our making.

I notice that Dr. Klingenberg has considered in his address the alternating-current stations supplying at 50 periods, and as this presumably is the easiest part of the supply to combine under one scheme, he has based his calculations on a station to supply these districts. This appears to me to be an ordinary business proceeding with a view to getting a quick return, that is to say, upon the narrowest case to show a justification for a unification of system and supply. But I think that the necessary change will hardly be brought about on an argument of this kind. He undoubtedly shows a saving, although this has been questioned by Mr. Snell. He has gone into it very fully, and I think there is little doubt as to the saving and the desirability; but I do not think any such argument or any such proposition would be sufficient to convert us from the present state of affairs and bring about something more desirable. There must be some great advantage to the public if any great change is to be made. In my opinion that advantage to the public is so changing the whole idea that the public can be supplied at a price which will make electricity practically universal and lead to its adoption for every conceivable purpose in this great city. Of course this involves a number of things. We have heard about the serious capital expenditure which has already been incurred, and Mr. Snell specially emphasized that fact; that is to say, we are so deeply committed that it is considered almost impossible to make a change, and if things only go on a little longer that change never can take place. But I have long felt that when electricity supply is so altered that electrical energy can be supplied at what I consider more nearly its correct price, it will develop on such a scale that the past capital expenditure will sink into insignificance. That, I believe, will be the true justification of the changes which must be made at some time later on.

Now Dr. Klingenberg has purposely stated that he deals with lighting, power, and traction, and for the moment leaves out of consideration heating and cooking. There again is the business instinct of the argument of dealing with what exists at the moment. But in this matter of electricity supply I think we have had almost too much of the present knowledge in relation to what may come in the future. When we look back a little way we see how very rapidly things have advanced and how what seemed impossible yesterday is being done to-day. It is simply repeating what I have already said in another form. My view as to the demand is this, wherever there is fuel combustion at present, there is the demand; and it is for electrical engineers to devise such means and improvements in the processes of conversion as will secure for us that demand. Fuel combustion within the cities will then be replaced by energy supplied electrically from without those cities.

Now there is one point in which I agree with Mr. Snell; namely, about stations distant from the area of supply. I

have often seen the remark attributed to me, or as part of Dr. Ferranti, what I have advocated, that power stations should be placed on the coalfields and the electrical energy transmitted to the great centres of demand. I do think, however, that the governing factor in the placing of the generating station, that is to say the station where the heat energy is converted into electricity, is the water supply. The water supply is enormously important to-day; and I see no method, so long as the converting process is thermal—that is to say, one in which there is a rise and a reduction of temperature—where the cooling water will not play a most important part. I have felt that the large generating stations necessary for electricity supply must be on the seaboard or on rivers of sufficient size to provide an ample supply of cooling water. As far as we are concerned in this country, I do not think that the coalfields, generally speaking, offer this facility. However, Dr. Klingenberg has shown that there is not much difference in the way of economy between the station near to the great centre of demand, and the distant station on the coalfields.

In considering the supply of electricity to the public, the problem, to my mind, is not how much more cheaply can we provide the existing supply, but for a little more revenue how many times can we increase the number of kilowatt-hours sold to the customer? Electrical engineers want to get a bigger revenue out of every customer, not in order to obtain a better price for the commodity they supply, but because they want to replace with their commodity what the public is at present spending money on in other directions; in other words, we wish to do everything electrically. Now the great means of reducing the cost of supply is this. I should say there are two great means; but the principal one is extending the time over which the article is sold. We all know the trouble of load factor. The railways are troubled with it in taking the people into the city in the morning and out of it in the evening; the restaurants are troubled with it by everybody wanting to eat at one particular meal-hour, and so on. But I think that it affects the electrical business more than any other. Electrical engineers have got to supply the public with what it wants, and to supply it in the way we want. The public want electricity when they need it, and we want to supply it throughout the 24 hours. We do not see our way, however, to supply light in that way. Light to-day requires a comparatively trifling amount of energy, and when we get that "cold light" about which people are talking, even more than now will the amount of energy required for lighting be small, and so the peak resulting from it will not be serious. The other great demand, of course, in cities is traction. Fortunately it is spread over many hours, and the load factor of traction is very good. The power load in big cities is also satisfactory, broadly speaking. The least satisfactory part is what is going to be a very big demand in the future, at any rate for a city like London, where the temperature is comparatively equable. I refer to heating and cooking. It is the business of electrical engineers to find out means by which heat that is generated electrically can be efficiently stored so that the public can have it when they want it, and yet we supply it when we want to, namely over the whole 24 hours.

Now there is another point. In laying out any area we must look, although it is perhaps far in the future, to what

Dr. Ferranti.

would probably be the demand if the whole energy consumption of the district were supplied electrically. I think that is a point of great importance. It need not interfere with the design or the execution of the present schemes, but it must be one of the matters for consideration, and it must be taken into full account before coming back to the scheme that it is decided to adopt for the moment. There is another thing I should like to say: London is the greatest aggregation of human beings in the world, and yet I do not think London is big enough to be considered alone. It is doubtful how far its stations can be really within its own area. Its fuel supply will certainly not come from within its own area. The industries and the demands of its population do not necessarily provide all the demands which should be supplied from any great electrical system. For these reasons I think that even London, although it is the most remarkable case in the world, is really not big enough to be considered alone. Of course this would apply much more to other cities in proportion as they are smaller, and I should like to emphasize this point. The areas of supply and their relation with adjoining areas of supply should be arranged upon an engineering basis and not upon a local authority or a city basis which has grown up for quite different reasons. Electricity supply, in my opinion, is a matter of national economy; a great deal depends upon it, and I think that properly carried out to its logical issue it is the greatest labour-saver with which we have any prospect of dealing. It can considerably affect the economy with which the country provides itself with its wants; and therefore the whole problem must be looked upon very broadly, bearing in mind its immense importance to the community.

Mr. C. Seabrook.

Mr. A. H. SEABROOK: I am afraid that I am not in a position to discuss this address in the detailed manner in which Mr. Snell has dealt with it. There are one or two broader questions, however, that have not been referred to, although Dr. Ferranti has covered a great deal of that ground. Early in his address Dr. Klingenberg refers to the control of such important public services as the electricity supply of big cities: I should like to draw the attention of those who are likely to control such undertakings in the future and of those who control them at present, to the kind of partnership arrangement which exists in both those cases that Dr. Klingenberg has dealt with, namely, Chicago and Berlin. Mr. Insull seems to have driven the better bargain by having to hand over only 3 per cent of his company's revenue, whereas Dr. Klingenberg has to give up 10 per cent to the Berlin municipality. Electrical engineers claim to be apostles of economy, and in view of the achievements of the industry I think they are quite entitled to that claim. There is one thing which we really ought to go into very seriously, and which is referred to by Dr. Klingenberg; that is the future method of raising steam, whether we are to continue to destroy what one may call the national asset, coal, by burning it on boiler grates as we do to-day, or whether we should not immediately look into the question of gasifying coal, thereby recovering its valuable by-products and using the gas for raising steam in boilers (a gas turbine is not available at the present time, but I think it is unwise to say that a gas turbine is impossible). One or two installations have been recently completed: the latest is that of the Accrington Corporation, but this has not been in operation

long enough for reliable figures to be published, although the results so far obtained seem to be very satisfactory. I am glad to see that Dr. Klingenberg deals at considerable length with the question of the generation of electrical energy at the pit's mouth. I think it is quite reasonable to say that electrical energy may not be economically generated in the Midland coalfields on account of the lack of condensing water, but Kent coal will within five years be an obtainable commodity. That coal is particularly friable, and I think it is not suitable for transport; but the Kent coalfield is surely near enough to the sea for all the condensing facilities required for power stations. I believe Dr. Klingenberg has had actual experience of supplying energy in this way, and I hope he will say something about it in his reply, because I believe he is gasifying coal now outside Berlin, generating electricity on the lines indicated and transmitting it to Berlin. We may not be able to go all the way in the case of London's electricity supply, but even if generation in Kent is not feasible at the present time it should not be overlooked. One or two large generating stations on the Thames during the next few years could eventually be supplemented by the generation of electricity at the pit's mouth.

Mr. W. C. P. TAPPER: Dr. Klingenberg's address has come at an opportune moment, when the minds of all interested in the future supply of electrical energy to London are more or less perturbed, some by fears and apprehensions, others by hopes and expectations, and others again by a sincere desire to bring the electricity supply of London up to date, and to put it on a really sound basis.

History.—The author's remarks on the electrical history of the three selected cities are very interesting. Up to a certain point Chicago and London have proceeded on somewhat similar lines, and I have no doubt if the whole supply of London could be put under a single controlling body that London would witness a similar rapid development to that which has taken place in Chicago. I am sorry that the author has not been able to obtain any figures for London later than 1910-11. These figures, owing to the very rapid increase in output during the last two years, are now quite out of date, and to that extent reduce the value of any comparisons based on such figures.

Factors determining the cost to consumers.—I entirely agree with the author on the very great importance of keeping down the capital cost of plant, etc., and also that within certain limits large generating units will effect this object. (In passing I may say that in this country there are undertakings of which the capital charges amount to more than the total of all the other costs.) The author advocates a single large station. Considerations of safety and the cost of high-tension transmissions would make it unwise to concentrate the whole supply for a city like London in a single generating station. The size of the unit would therefore be determined from the number of stations decided upon, and the amount of spare plant required in each. He also advocates uniform alternating-current distribution, presumably three-phase. On this point I entirely disagree with him. In the first place, in London it would cost several million pounds to convert the distribution networks and the consumers' wiring and apparatus to such a system; and any advantage gained

would be more than counterbalanced by the heavy capital charges on the cost of such alteration. Again, with alternating-current distribution the supply authority has little or no control of the power factor. This will involve from 15 to 20 per cent larger generating plant, transmission cables, converting plant and distribution cables. This increased capital cost would form a very serious set-off to any savings in other directions. If the distribution is by continuous current, effective control of the power factor on the high-tension system is obtained. Another important point is that power consumers are more easily obtained and retained on a continuous-current supply than on an alternating-current supply. Under the heading of capital charges the author refers to the question of the allocation of profits. I am in entire agreement with him on that point. The municipal authorities should not participate in the profits, but they should secure that a certain proportion of the profits should be given to the consumers in the shape of reduced charges.

Utilization.—I am not quite clear as to whether the author attaches any importance to the distinction between the terms "utilization factor" and "utility factor." The first appears to be the annual load factor with reference to the maximum safe load on the plant, and the second with reference to the maximum observed or peak load on the plant. In determining the charges for new business the first (*i.e.* safe plant capacity) may be taken into account, but in ascertaining actual costs from time to time the peak load must of course be used. The author does not appear to have allowed for the effect of diversity factor in determining the possible selling price. I am sorry that Dr. Klingenberg has chosen the shilling as his unit of money. We are so used to thinking in £s per kilowatt and pence per unit, that shillings and cent-shillings considerably increase the difficulty of following the author's figures. I also regret that the author has introduced another method of arriving at the cost of giving a supply to different classes of consumers with varying load factors. The suggestion of dividing what are called the standing charges by a number representing kw.-hours must involve misleading results. Nothing can be simpler than the principle laid down by Dr. Hopkinson, and elaborated by Mr. Arthur Wright, of dividing the total cost into standing and running costs, and stating the first in terms of so much per kilowatt per annum, and the second in so much per kw.-hour. The author states that he has shown it is possible to generate at the same prices for lighting, power, and traction, and then states that, as prices can be kept up for lighting, traction can be reduced (presumably down to or below cost). This statement contains, in my opinion, two serious fallacies. First it is an unsound principle to make a surplus on one class of supply and use that surplus to sell at or below cost to other classes. Again, the author ignores the diversity factor, as I have previously pointed out. If this factor is properly allowed for, it will be found that, contrary to the author's statement, lighting, power, and traction do not cost the same, the cost of each class of supply bearing a close relationship to the diversity factor of that class. The lower the diversity factor the greater the cost.

One suggestion put forward by the author opens up great possibilities. I refer to the making of gas, burning the same under steam boilers and selling the by-products. The gas companies are experts in the making of gas. Why

should not the gas companies and the electricity supply industry co-operate, the gas companies supplying the gas at a low rate to the electricity supply undertakings, and the latter burning it under boilers and generating cheap electricity thereby? It may be said that it would be more economical to burn the gas in a gas engine, but we must remember that a 30,000-kw. gas engine or gas turbine has yet to be built. Can the author give any information as to the use of single-core lead-covered cable for extra-high-tension alternating-current work, and as to the sheath losses in such cables? With regard to overhead transmission, I think it would be quite impracticable to supply a city of the size of London by overhead lines. If the Post Office find it necessary to put their trunk lines underground in the country districts to prevent interruption, it is obvious that the power conductors supplying London would also have to go underground. This being so, it is probably cheaper and certainly safer to bring coal to London.

Mr. W. B. SAYERS (*communicated*): I wish to refer to Mr. Sayers' three significant sentences: two of these occur in the address, and the third was uttered in substance by Dr. Ferranti in the discussion. Dr. Klingenberg remarks: "What is necessary is to alter the nature of the consumption." About two years ago I contributed an article to the *Glasgow Herald* on the "Cost of Electricity Supply." In that article I endeavoured to bring home to the public—especially those responsible for the conduct of industrial concerns—how a recognition of the facts which govern the cost of electrical energy, and conformity wherever possible with the principle of taking a supply for any purpose at the time of day or night when the demand on the station is a minimum, might secure to them special low terms, and would in any case react to their ultimate advantage by enabling the suppliers to reduce the price to all consumers. Switches operated from the supply station can of course be employed to secure that the conditions agreed upon are carried out—at least in some cases. The problem is to get those of the public who can determine or influence the matter to appreciate its importance from the point of view of the public welfare, efficiency, and economy, and then have the public spirit to act although the immediate visible gain or advantage may be small.

The second sentence by Dr. Klingenberg and the remark by Dr. Ferranti I will deal with together, as the latter sentence emphasizes the objection to the former. The author in his concluding remarks says: "One might be able to secure protection against a rise in the price of this fuel by the acquisition of a coal-mine," and Dr. Ferranti said in effect, "The aim of electricity supply concerns must be to replace combustion wherever found within the city." The ideal expressed by Dr. Ferranti is what we look forward to ultimately, but it gives an undoubted and emphatic negative to the suggestion often made before and now discussed by Dr. Klingenberg of a large bulk-supply station or stations at the pit's mouth. After all the time, labour, money, and experience that have contributed to make electricity supply dependable and reliable as it is to-day (which reliability is a *sine qua non* to its continuance and progress), it is preposterous to propose to make the City of London dependent for light, power, traction, heating, cooking, and every other purpose where energy is required, on a single coal-mine, or even group of mines. Suppose the coal-mines were purchasable at a reasonable price. Is there any coal-mine

which is immune from possible failure through accidents such as fire, water, explosion, faults in the seams? Or against strikes or disputes among miners and workmen? Compared with this main question of immunity from risk of failure or interruption of supply even the matter of condensing water is trivial. It requires but a thought from this point of view to arrive at the conclusion that not only must any bulk-supply station on which London may be largely dependent for its supply of electrical energy be located where there is abundant water as well as fuel supply, but without doubt it must be possible to maintain the supply of fuel of any description—coal, oil, or other combustible—both by land and by sea transport, and in case of emergency to ensure the security of such supply by means of the national resources.

Dr. G. KLINGENBERG (*in reply*): In replying to the questions that have been asked, I will first refer to the points raised by Mr. Tapper. I am not advocating for large cities only a single power station: the reason why I have based my calculations for the numerical example in the case of London on one station is because, under the assumptions made, the capacity of the station amounted to only 80,000 kw. at the start and 140,000 kw. after the first extension. This I consider in no way excessive, especially if the sectionalizing of the station is provided for, either by reactance or through the feeding system itself.

With regard to the question of continuous current or alternating current for distribution, I entirely disagree with Mr. Tapper. I consider alternating current in no way inferior to continuous current as far as the convenience of the consumers is concerned, and I would mention only the transformation of an alternating voltage and the simplicity of polyphase motors. As regards cost, there can be no doubt that a pure alternating-current system comes out cheaper in a good many respects. It appears to me that Mr. Tapper is over-estimating the effect of the power factor, which, assuming for instance the present load conditions in London with 60 per cent of lighting, promises to prove quite satisfactory, and which could be regulated to almost any desired value if the percentage of traction be increased, as certainly will be the case in future. I am not proposing, in considering the possible improvements of present systems, to change the existing continuous-current distribution at once into alternating-current distribution. From the example which I have given in my address it will be seen that I am advocating a postponement of any alterations to the existing distributing system because the improvement achieved as regards the total selling price compares very unfavourably with the capital involved in such alterations (see Table IV, Equations 2 and 3). I also emphasized, as the principle for proceeding with alterations, the allocation of the various costs by separation and studying their dependence on the utility, thus determining the gradient of improvement (as regards the cost of energy) on the various parts with a certain amount of extra expenditure. Having once defined these gradients for all parts of the system, by applying the same to the formula for the cost characteristic the whole problem as regards the programme of the alterations becomes very simple, and therefore helps considerably in settling the political and financial questions. In this way it will certainly be found that in large cities extensions with continuous-

current generation are out of the question, and that independently of existing continuous-current distribution systems the whole feeding system, and as far as possible the extensions of the distribution system, should be carried out with alternating current at as high a pressure as possible.

It has been pointed out in the discussion that in determining the factors bearing on the cost of electricity, I had overlooked the diversity factor. This is not the case. By referring to Fig. 4, which gives the load factors under any combination of light, power, and traction in large cities, it will be seen that these include the diversity factor, or to state it differently, that from these curves the diversity factor can be determined under any combination of traction, power, and light. For instance, under the conditions assumed for the diagram Fig. 3, viz. 25 per cent lighting, 25 per cent power, and 50 per cent traction, the load factor according to Fig. 4 works out to 39.3 per cent, which means that the diversity factor under these conditions is about 88 per cent. I am paying the greatest importance to the results shown in Fig. 4, as they form a step forward in the direction of positive knowledge and simplification on a most important point where such a wide field for guesswork was left. My statements as regards the costs for lighting, I admit, may be misleading. In saying that under certain conditions these costs were equal to those for power and traction, I wish to lay stress on the costs in the power station only, a difference of course coming in when distributing the small demands to private houses, as compared with the large supplies required for power and traction.

Mr. Seabrook has asked for further particulars in regard to the gasifying of coal in connection with the Berlin supply. Close investigations which were made some years back did not prove sufficiently promising at the time. The conditions may be different with new developments and if a power station of large capacity is erected on a coal-field in the vicinity of industrial centres. As the matter stands at present, this requires careful study in every individual case.

I entirely agree with Dr. Ferranti as regards the great prospect for electricity if this could be supplied at its "correct" price; but after a close study of the question in general and from my experience I am less optimistic about the time in which such progress will be made in cities. Past history has shown that the supply of electricity is not a highly paying business, in fact many companies are permanently suffering from their selling prices being fixed too low. Under such conditions it is not an easy matter to convince the public that this will be different in future and therefore to find the capital for proceedings on a very large scale. London appears to be situated not more favourably in this respect than other cities, in fact the comparison in Fig. 5 shows that the selling prices in 1911 were considerably below the cost which one would call a normal price, having regard to the capital charges. Even if the progress of the demand is taken into consideration, as I did with the numerical example of London (I assumed an increase of the demand in one to two years of about 28 per cent), I think such a problem generally requires careful study as regards the programme for the reconstruction before one is able to show an economical advantage at all in the near future,

Dr. Klingenberg.

and more so if no margin is left in the existing selling price for current.

In reply to Mr. Snell's remarks I wish to make it clear that I have not recommended for London the erection of a power station at the coalfields. I do not feel in a position to advance any recommendation at all on a subject requiring such intimate knowledge of very special conditions, about which only local engineers can judge. The object of my Address was merely to discuss generally the principles of electricity supply in large cities as they appear to me from past experience and with present knowledge. In applying these principles to a numerical example it appears natural that I should base this, as regards the main and initial assumptions, on such values as would approximately correspond to the conditions over here. The results I arrived at are therefore more or less mathematical and outside any political considerations.

As regards my calculations, Mr. Snell doubted the figure of 170s. per kilowatt installed which I arrived at for the distant power station, mainly in view of the difficulties of the water supply. I admit that I have assumed it to be possible in this country to find satisfactory conditions for cooling arrangements at or near the collieries, but taking the worst case, viz. that cooling towers would have to be installed, the above price still seems adequate and in accordance with the cost at which new stations on the Continent have been built. With regard to the consumption of water, I cannot imagine that there would be any difficulty in providing for this, even with a very large power station: it should also be borne in mind that the loss of water has considerably decreased with the improvement of the steam consumption, and I estimate that a new station with large sets would perhaps require only half the amount used in the existing London stations based on an equal output.

Further, Mr. Snell has criticized the figure which I have allowed for land required for the overhead lines, 600s. per ha. was reported to me as a liberal allowance under the conditions. When considering this point it should be borne in mind that it will not be necessary to buy the assumed strip of 15 metres for the whole length as a freehold. At certain parts I expect it would be possible to lease the right for the pole lines on more favourable terms, and the freehold land could still be used to a great extent for general purposes. With this in view I believe that the amount which I have allowed can be considered as an approximate average figure, but even a considerable increase in this item would only mean a small percentage of the total cost which I have taken for the lines. I agree with Mr. Snell that this question of land forms a disadvantage in densely populated countries as compared, for instance, with the United States, and I may say that this is one of the reasons in my opinion why engineers in European countries should pay more and more attention to the use of high-pressure cables for long transmission lines. It is remarkable how small the difference in cost works out (see Figs. 9 and 10), when comparing overhead and cable transmission for a pressure of 100,000 o ts.

Mr. Snell has also touched upon the question of safety in the case of a supply from distant stations. This is certainly a very important point for an electricity supply to a city. I am of opinion that transmission over distances such as those on which I have based my calculations can nowadays be considered sufficiently safe, especially if a certain amount of plant is kept as a spare near the cities, which will most probably be the case in every large city for a considerable length of time. The possibility of using cables instead of overhead lines would no doubt improve matters still further.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 18TH DECEMBER, 1913.

Proceedings of the 559th Ordinary Meeting of the Institution of Electrical Engineers, held on Thursday, 18th December, 1913—Mr. W. DUDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 4th December, 1913, were taken as read, and confirmed.

The list of candidates for election and transfer approved by the Council for ballot was taken as read, and was ordered to be suspended in the Hall.

A paper by Mr. H. C. Gunton, entitled "The Employment of Power in H.M. Post Office" (see p. 109), was read and discussed, and the meeting adjourned at 9.55 p.m.

DISCUSSION ON

"A TWO-RATE TARIFF SYSTEM WITHOUT TIME-OPERATED CONTROL."*

MANCHESTER LOCAL SECTION, 18TH NOVEMBER, 1913.

Mr. J. FRITH: In discussing this question it is well to consider what are the objects of a tariff. They can be broadly divided into two distinct categories. The first aims at doing justice to every consumer connected to the mains, i.e. endeavours to charge every consumer in some way proportionally to what he costs the supply undertaking. The second aims at obtaining the maximum financial success for the supply undertaking. Broadly speaking, the policy in the case of a municipal undertaking should approximate more toward the first, and that of a company to the second of these categories. It is hardly possible to explain to the lay consumer the meaning of the term "load factor," but it can be explained to him that if he wants his supply at the same time that everybody else is wanting it, it is only fair that he should pay more than if he were taking his supply at a time when other people were not using electrical energy. I think when we have decided which of the above aims we are trying for, a few of the other conditions of a good tariff are worth discussing. The first thing is that a tariff should be understandable by the customer. He should be able to estimate what the supply is going to cost him. The next point is, of course, that the tariff should encourage the free use of electricity. Personally, I think the tariff best adapted to do this is a fixed charge per annum and a small price per unit irrespective of the use made of the energy, but I am not quite sure how the fixed charge should be based. The rateable value method is simple, but it is not easy to see why an electricity bill should depend on the size of a garden. I wonder whether such apparatus as that described in the paper will give results which can be easily understood by the customer and which will gain his approval; it would be interesting to know if any such information is available.

Mr. S. J. WATSON: I myself have not had any experience in the use of two-rate meters. The most important point to be borne in mind in framing any tariff is that it can be understood by the consumer. A few years ago many undertakings charged on the maximum-demand system, but I do not think that there are many to-day who continue to use that system. It was condemned because consumers could not understand it. It is doubtless quite correct in principle, but it is impossible to make various classes of consumers understand why one class should pay at a higher average rate than another. I feel convinced that for a general supply for domestic and similar purposes some method whereby only one circuit inside the house and one meter are required is the simplest and the best that can be adopted. It is only a question as to the basis of the standing charge. People know that the municipal rates are based on the rateable value of their property, and they know the rent which they have to pay; they can therefore tell approximately what their liability will be if the rateable value

system is used. Some time ago the chief engineer of one of the London supply companies explained to me how very different are the conditions in the residential districts of London from those which obtain in Lancashire manufacturing towns. He pointed out that in order to sell as many units per annum as are used by a 5-h.p. motor operated during factory hours, it would be necessary to connect up about 150 small heaters or similar appliances on the premises of his domestic consumers.

Mr. C. C. ARCHISON: In Rochdale my experience is entirely different from that of Mr. Watson at Bury, as I certainly find that the public-house consumers are those who appreciate the maximum-demand system. It seems strange that two towns so near together as Bury and Rochdale differ in this respect, and it emphasizes Mr. Watson's remarks as to how much greater must be the difference between Lancashire and London with their entirely different problems. Mr. Watson also mentioned that the demand indicator appeared to him to be a correct method of charging. I cannot quite agree with him on that point, but whether the maximum-demand system is or is not correct it is certainly a very difficult tariff to use. It can be explained to the consumer and he may fully understand it, but at the end of the quarter when he receives his bill he has probably forgotten all about the explanation. In regard to the flat charge based on the rateable value with a uniform price per unit, the remarks this evening have called my attention to what appears to be a weak point in that system. Take the case of two houses of similar size supplied by electricity, one having no garden and the other a large garden; each may have identically the same number of lights and consume the same amount of electricity, but the man with the large garden, if charged on the rateable value system, will pay a larger annual sum than the man without a garden. Is it reasonable to make this difference in the price? As against this, I should like to call attention to Mr. Frith's statement that apparently the system of charging adopted by municipalities is equity and that of companies profit. Surely although we try to bring equity into it the municipality has also to aim at a profit; but whether we wish to bring in equity or not, a low price per unit is useful, no matter what other charge there may be. Possible consumers always quote the charges paid in other towns; and in almost every case, whatever the other rates may be, the lowest figure is stated as being the charge for the class of supply required. Only during the last few days the Bury tariffs have been quoted twice to me, and I may point out that the price mentioned by the possible consumer was only applicable after a certain number of units had been consumed at a higher rate. It will be seen that each one tries to bring in equity and at the same time look after the profit. If it is possible to state a low price per unit it is taken into consideration by the consumer and further

* Paper by Mr. H. H. Perry (see p. 42, No. 223).

charges almost overlooked. Perhaps this idea is somewhat of a "catch-penny" business, but it pays in the long run.

Previous speakers have advocated one circuit for all purposes; in some ways I should do so myself as it is certainly convenient to have only one meter, but at the same time I should like to see a uniform price. There is quite enough to do without adding to the clerical work, as we find to our cost in Rochdale where we have 28 different prices to deal with; perhaps it is not readily appreciated how easy it is to increase this kind of work and how difficult it is to reduce it. While one circuit no doubt sounds the right thing, experience does not always prove it to be so. Probably all supply engineers know how a consumer who first installs a certain number of lights and later wants to add to these, naturally not wishing to spend more money than is necessary to provide the original installation, finds that his wiring is not sufficient and that it means starting from the service terminals and installing new wiring to the various points of the house where it is desired to increase the supply. This question is very closely allied to the undersized plug circuits; as a supply engineer I do not think it matters whether the undersized plug circuit is in order or not since this is a matter purely for the consumer and his contractor. If it were necessary to inspect all the installations in order to see that suitable sections of wire were used it would mean that a spare man would have to be employed, and even then we could not be quite sure without having a man permanently on the spot while the installation was being carried out; this of course might not be convenient. I think the present arrangement of leaving it to the consumer himself is the only reasonable method, as he will be certain to find out for himself sooner or later, and it remains then for the supply undertaking to refer him to the contractor who wired the installation. Also in regard to one circuit, in this paper a meter has been described which may be utilized for one circuit, but the author has been cute enough to provide also for two circuits, and the meter has been designed to meet the requirements—much as they appear to differ—of Lancashire and London. The whole question of tariffs seems to me to remind us that we have to get as much money as we can from consumers, and if there is any instrument that will ensure equity at the same time as profit we should endeavour to find it.

Mr. E. M. HOLLINGSWORTH: The author has put forward a very ingenious and no doubt quite practicable device, but I am afraid it has arrived too late in the day, for central-station engineers are rapidly getting away from the complicated and costly two-meter systems. In proof of this I would point to the general adoption of one or other of the "contract systems" which are proving satisfactory to the user and the supply undertaking alike. The author states that no paper on the subject of tariffs has dealt with the question of giving the consumer a lower rate during the light-load hours. Surely, a contract system does give such an advantage, and such systems have recently been the subject of several papers. I do not agree with the author in his reference, on page 43, to the diversity factor in connection with the supply for power. In determining the charges to large power users, the diversity factor plays no part; it is entirely a question of "value of service." To bring in such users, the supply authority has to prove that it is to their advantage to adopt the supply, hence the low

charges at present prevailing. One of the advantages claimed for the use of the author's switch is that a consumer can tell what his cost per unit will be. It is my experience that the user is more concerned about the total cost per quarter or per annum than about the cost per unit; and in any case this system does not give the average cost.

Mr. P. P. WHEELWRIGHT: My experience of a two-rate tariff and two-rate meters, although I have only tried them on a small scale, is, I regret to say, far from satisfactory and bears out the disadvantages mentioned by the author. I quite agree that there are places where the system and apparatus described in the paper could be used with success, but I think that the following points ought not to be ignored, and in many towns are sufficient to prevent the system being put into operation. The use of lighting circuits for heating apparatus may lead to trouble and possible disaster, as after all when purchasing a small radiator or a kettle the consumer has only a very vague idea what the probable consumption will be. Consequently when the radiator causes the fuses to blow, and lampholders and lighting plugs to overheat, considerable annoyance is caused and the supply department is called in, with the result that the consumer is notified that the wiring is not suitable for anything but small apparatus. The contract prices accepted during the last few years for wiring large installations bear out my contention that after all there are few houses where the double use of the wiring may be carried out with safety and satisfaction to the consumer. The question of satisfying the consumer that his meters are registering correctly, should he doubt it with this two-rate apparatus in use, is one that cannot be overlooked; personally I can see considerable difficulty in explaining any sudden increase in the higher priced units in a quarter's account. The suggestion that the capital outlay required to install this apparatus with an extra meter may be overcome by the payment of a rent is, I think, wrong. I maintain that the price of energy ought to cover the cost of the necessary measuring instruments, etc., as in all other trading concerns. At the present time I think most supply departments will acknowledge the difficulty in getting consumers to notify them of any extensions which they may make in their lighting installations or any increase in heating or other apparatus. Consequently where the instrument is in use it is very liable to be considerably overloaded, if not burnt out. I quite agree with the author that the simplicity in working is an advantage of the instrument, but simplicity in the method of charging for energy is the only point that the consumer really appreciates.

Mr. A. G. COOPER: This paper takes me back many years. When I was with the City of London Company in 1892 I brought out a meter on practically the same lines as that described in this paper. The only alternating-current meter at that time was the Thomson meter, and I took out a patent for splitting the windings. The British Thomson-Houston Company bought the patent and I gave the foreign rights to the French meter company. Very few meters were sold. Unfortunately at that time all electric light stations were run on more academic lines than at present. The stations then were not content to know how much money they had to receive, but also wished to know what was the loss in distribution. The meter would not indicate whether one unit had been used for lighting at 6d.,

Mr. Hollingsworth.

Mr. Wheelwright.

Mr. Hollingsworth.

Mr. Cooper.

Cooper or 3 for power at 2d. (I have assumed these prices.) I wanted to charge according to the rateable value and get rid of the meter; I therefore took about 40 consumers and found that the conditions in the different cases varied so widely that I came to the conclusion that no tariff could be framed to meet all cases. I also found that the demand indicator was disliked by the publicans. The only thing to do with the latter was to charge them all on the 3-hour rating, i.e. one hour at 6d. and two hours at 2½d.; they were then all satisfied.

Peck. Mr. J. S. Peck: It would appear that the idea underlying Mr. Perry's instrument is that the off-peak load on the station can be increased by offering the consumer a low rate for his lighting, provided this is kept down to a small percentage of his usual load. It is purely a matter of opinion, however, whether there will be an increase in the net profit when it is considered that the increased load is supplied at a lower rate, and also when the extra cost of the automatic switch with the necessary maintenance charges are given due weight. In Fig. 4 an arrangement is shown by which the greater the power load the greater the lighting load which can be obtained at the low rate. This seems to me to be wrong in principle; for if it is desired to keep down the peak load, then the arrangement should be reversed so that the greater the power load at any time the less the lighting load which can be taken at the same time and at the low rate. In regard to the construction of the instrument itself, I should anticipate more or less trouble due to burning at the contacts; for while it is true that only a low voltage has to be broken at the switch, the forces for operating the moving element are very small, and it may happen that the switch can stick in the balanced position, thus causing an arc to continue for a sufficient time to do serious damage. In any case the switch in its present form would only be suitable for use with very small currents. The author states that there is a loss in the switch of 4 watts with continuous current, and of from 8 to 10 watts with alternating current. If the loss on alternating current is 8 to 10 watts, the number of volt-amperes across the switch will be several times that figure on account of the poor power factor, so that the voltage drop will be very considerable.

kinson. Mr. H. T. WILKINSON: I should be glad if the author would give us some examples of the actual operation of this switch in practice. I should like to have one or two instances; the prices applying to the two rates, and the average price obtained. When I was with the Lancashire Electric Power Company a few years ago we found it a great mistake to talk to consumers in terms of units. In one case one of our engineers was trying to convince a prospective consumer that 0·8d. per unit was a low price for him to pay. He could not impress this on the customer, so told him that in some places 5d. or 6d. was charged. The reply was that he did not know what a unit was, but 5d. seemed a lot to pay for one of them. The Acme Spinning Mill at Pendlebury, the first electrically-driven cotton mill in this country, was supplied at a fixed sum per annum for driving and lighting. We took on weaving sheds, and charged at so much per loom per annum. We found this worked out satisfactorily, the price of course varying with different types of looms.

Mr. W. CRAMP: There is one very important point in this paper which has been barely touched upon, and deserves much more comment than it has received. It is to the effect that under the proposed tariff the smaller the amount of energy used the less is the price paid per unit. Consumers hitherto have been encouraged to take as much electrical energy as possible—when they have taken as much as possible for lighting, the supply authority offers a lower rate if energy be taken for some other purpose. Here, however, the author has suggested a system whereby the customer using lights only will receive a distinct advantage. The man at whom the author is aiming is he who uses a few lights for many hours. If this system were adopted, the electricity bill would be of this character; for a few lights, a low rate; for more lights, a higher rate; and for lights plus power, a lower rate again. Mr. Wilkinson is, I think, quite correct in stating that the rate for electrical energy should be expressed in a unit which consumers can understand rather than in an electrical unit. Take a flour mill for instance; if the cost of electricity can be expressed at so much per sack of flour produced, the miller knows just what is meant.

I should like to say a word from the consumer's point of view about the two-circuit system of wiring. The fact is that a very small proportion of people own the houses in which they live, and consequently two cases are constantly arising: (1) If the landlord or the previous tenant has done the wiring, it is more than likely that the single system has been employed, and the new tenant has a strong objection to paying for the installation of a power circuit. (2) If the tenant has the whole wiring to do he grudges very much the cost of a double system which at the end of a short lease becomes the landlord's property.

A very important question which arises out of the paper is the cost of apparatus installed by domestic consumers to make use of the power rate. I refer to apparatus for cooking, heating, etc. The suggestion which the author makes in this connection "that the supply authority should have a hiring department" is a very good one, but in my opinion to charge for hire without maintenance would be a mistake. The fact is that domestic consumers experience very great trouble owing to the fact that there is so little standardization of parts of domestic apparatus, and also that the cost of repairs is so high. As an example, an electric iron may cost the consumer from 12s. to 15s. It may give trouble owing to the breakdown of the flexible wire or the burning-out of the heating unit. In the latter case on returning the iron to the makers it will often be six weeks before it is repaired, and the cost of the repair may be half the cost of the iron. So long as such cases occur domestic consumers will be necessarily shy of purchasing apparatus, but if they could hire it on a maintenance agreement they would be glad to do so. Such hiring with maintenance would lead to two very desirable results: First, in towns like Manchester the electric apparatus would be on a footing similar to the gas apparatus; and second, large purchasers like the supply authorities could bring pressure on makers to improve and standardize their wares. With regard to the difficulty of using domestic apparatus upon ordinary lighting plug circuits, I should like to say that if the lighting wiring has been installed to a proper speci-

cramp. cation there need be no fear at all of overloading the lighting plugs so long as not more than 1 kw. at 200 volts is used per plug. I consider that a great deal too much has been made of the danger of over-running wires and flexibles. It is quite possible, and usually quite safe, to take 1 kw. at 200 volts from an ordinary lighting pendant.

Barlow. Mr. F. BARLOW: I should like to take the author if at the end of a quarter a check can be taken on the readings for the preceding quarter; if not, how is it possible to be in a position to enforce the charges should the consumer dispute them?

Professor E. W. MARCHANT: Speaking as a consumer, I am of opinion that it is an advantage to know, approximately, how much one will have to pay at the end of a quarter, and I think that any system which leaves any doubt about it is not altogether satisfactory from a consumer's point of view. That seems to me the objection to the maximum-demand system, and to a certain extent to the system described by the author. I also have doubts as to how the working of the author's switch is to be checked. If the switch sticks, it seems to me that there might be a very heavy charge due to the high-rate meter. I should like to know whether there are any devices on the switch which will provide for such a contingency.

Perry. Mr. H. H. PERRY (*in reply*): The origin of my idea first centred around the two-rate clock, which as a system has very distinct advantages and has given good results in practice where tried. The disadvantages mentioned in the paper, however, outweighed the claims of that system for general use. The advent of heating and cooking by electricity suggested that a two-rate system might be used if the switch could be automatically controlled; for there is this curious anomaly, that a relatively high price is charged for lighting and a very low one for heating. So long as the domestic consumer uses the supply, it matters little for what purpose he uses it—if light is not required at certain hours he may be induced to use the supply for another purpose. When the time comes for offering an average rate of, say, 1½d. or 1¼d. per unit, then the central station can depend on a regular day load.

Mr. Frith referred to the desideratum of charging a fixed price and a small rate per annum. If all consumers are satisfied, this is an excellent plan. I am asked for information regarding the operation of this two-rate switch. It has only been tried experimentally, but it has been subjected to very exhaustive tests under the most varying loads. I am rather surprised that nobody has mentioned electric heating and cooking and the results therefrom. It seems to me that a new field has opened up rapidly, and it would have been very interesting if members had given their views as to the desirability of pushing this new departure.

Mr. Watson laid emphasis on the fact that whatever system was chosen it should be capable of being understood by the consumer, and he approved the principle of the maximum-demand system. I am perfectly in agreement with him there, but the system, as stated, has its limitations. If a flat-rate system can be adopted on a primary house assessment charge, it is possible to have one meter for the whole supply, with heating and lighting at the same rate, but the short-hour consumers with a high maximum demand, such as shops, derive too great a benefit.

Mr. Atchison laid stress on the clerical work side of the question, and in consequence generally prefers a primary charge system. I am afraid the clerical work must always be a trouble, and I do not see how it can be got rid of; but if extra business can be derived with advantage, this department must necessarily increase. He also raised the question as to the size of the contacts in the switch shown. They are quite large enough to carry at least 25 amperes. The instrument described will only have to carry a quarter of this load on the low rate, and I do not think there is the least chance of any trouble, since on the high rate, the greater the load the greater is the pull on the contact. The point where there may be trouble is at the position of equilibrium, but the auxiliary contacts are so designed that the switch is practically never broken. The switch operates equally well on either alternating current or continuous current.

Mr. Hollingsworth claims concessions for light-load usage by other systems, and while this is true for some of them, they do not bring that knowledge clearly to the consumer—as stated in the paper. I think he rather misses my point as to the diversity factor when domestic tariffs are considered. Here the power takes the form of heating or cooking, and is to-day a class of business eagerly to be sought after, and in a few years' time likely to cause a further revision of tariffs. Should this prove to be the case, the diversity factor will enter very largely into the calculations. As regards being late in the field with the proposed tariff, I am inclined to the belief that it may be too early.

Mr. Wheelwright asked for some information as regards the working of the switch, and he rather doubted the reliability of the same. He advocated that there should be no meter rent, and I quite agree with him if the rent can be omitted and its equivalent included in some way in the tariff. If the consumer doubts the sub-division of energy between the high- and low-rate meters, it should be a simple matter for the inspector to show the switch in action on a critical load for which it is set.

I am interested to hear from Mr. Cooper that he patented a single meter for two-rate use as far back as 1894—I was unaware of the existence of such a patent. He mentioned the question of lighting circuits being inadequate. As far as the general size of wiring goes for this system or any other, it is of course impossible to add heaters and use them indiscriminately over a house not originally wired for their inclusion. If large radiators or heaters are going to be used, it invariably means new circuits. This is one of the greatest troubles in persuading people to add to their existing circuits. It leads to obvious inconvenience and they hesitate a long time before giving their approval to a structural disturbance. I suppose time will show whether this expression of opinion is the same all over the country when electric heating and cooking are more generally adopted. When electric cooking is adopted, the present consumers' circuits need not be disturbed, since cooking is usually carried out in the kitchen or scullery near the meter, and only a very short length of additional wiring will be required.

Mr. Peck raised a point with regard to Fig. 4, and thinks the conditions as regards load on the opposing windings should be reversed. The argument may be amplified:—If a valuable consumer of power is to be encouraged, it

Perry will be safe to give him better terms for his lighting, should his heating peak, if one only, not overlap the normal peak on the system due to lighting. If he had three peaks per day due to heating, as instanced at Derby, it would still pay the supply authority to allow one peak to overlap the lighting owing to the increased revenue from the day load. It is not suggested that the consumer should get the whole of his lighting at the low rate, but a greater proportion than in Fig. 3. Mr. Peck also raised the question of arcing at the contacts when the apparatus in use with the switch has a large self-induction. The switch has been tried under such conditions and found to work very satisfactorily.

Mr. Wilkinson asked whether the switch had been actually used in practice. Owing to the unexpectedly early date of this paper, I regret to say "No," but I hope in a very short time to give the results of actual working. As regards the rates proposed, the high rate should certainly not exceed that charged at present.

Mr. Cramp raised the question of the consumer with a large number of lights and whether he gets any benefit from the use of the proposed two-rate system. The object in view with the proposed system is to meet the rational demands of an ordinary household, irrespective of the number of lights. There are hours when only a few lights are required, but the majority are "necessitated" lights and are kept on for long hours—such loads are valuable and a low tariff is naturally offered. But household customs

demand at other hours—all too few—a number of lights Mr. Perry approaching the maximum, for which the generating station must be prepared every day. It is fair to charge a higher rate for a perfectly logical use. If the same consumer adopts heating or cooking by separate circuits, it is true that his average rate does decrease for the dual supply, since heating could not possibly make any headway unless a low rate were given—and its load factor should warrant the low rate. It is inconceivable that any ordinary consumer would designedly use only a quarter of his maximum number of lights in order to gain the low-rate charge.

The answer to Mr. Barlow's question is contained in the reply to Mr. Wheelwright, and, moreover, much the same contingency might arise with the instrument on the maximum-demand system. If it would facilitate matters, a counter could easily be fitted to the automatic switch, or a relay indicator placed in some conspicuous part of the premises to meet the requirements in special cases only.

In reply to Professor Marchant, the private consumer who is content to make regular payments for his supply, however used, would probably prefer the flat rate or the contract rate. Under the proposed system he would certainly pay no more, and very probably less. Owing to the decided gravity action, there is no tendency for the switch to stick on the high-rate side, other than fusing action; which contingency has already been discussed. The indicator would at once show a false position.

DISCUSSION ON

"THE CHARACTERISTICS OF INSULATION RESISTANCE." *

BIRMINGHAM LOCAL SECTION, 26TH NOVEMBER, 1913.

Dr. C. C. GARRARD: The characteristic shape of the moisture conductivity curve found by Mr. Evershed is of great interest, and in view of the microscopical and other researches given in the paper one is rather diffident of expressing any doubt as to the underlying theory of endosmosis which seems to fit in excellently with the facts of the case. I should only like to ask the author if he has considered whether the phenomenon cannot be explained on the basis that the conduction of the moisture within the insulator is electrolytic in character. If two electrodes be placed in a vessel of water, and a gradually increasing voltage be applied, it is found at first that the current flowing is very small, but that after a critical value has been reached the current very rapidly increases, that is to say the electric resistance rapidly decreases. This phenomenon, with a single cell, only occurs between zero pressure and a pressure of, say, 2 or 3 volts, but in a porous insulator one can regard the moisture as being split up into a large number of cells in series, so that the pressure over which the action will be shown might be several hundred volts, as is the case in Mr. Evershed's experiments. On this basis could also be explained the fact found by the author that when the insulator is very

wet the conductivity follows Ohm's law; for, with a very wet substance, instead of a number of electrolytic cells in series we only have one, and a variation in resistance over the first volt or two is of no effect when working with a pressure of several hundred volts. I do not put this theory forward in any sense as a rival of Mr. Evershed's, as I have not had an opportunity to put it to any experimental test. I merely mention it as an alternative suggestion. Possibly Mr. Evershed as a result of his prolonged work on the subject has sufficient experimental data to upset it. The electrolytic action might also account for another phenomenon which I have often observed when testing the insulation resistance of apparatus, and that is that it improves if the testing voltage be applied for a long period.

One outstanding feature of the paper is the impossibility of using porous insulating materials in electrical machinery. At the present time these are of course no longer used by up-to-date manufacturers. The fibrous materials such as cotton, paper, and the like, are used simply as mechanical carriers for the insulating compound. The experiments showing that even impregnated windings absorb moisture are remarkable. They do not, however, bring out the im-

* Paper by Mr. S. Evershed (see p. 51, No. 224).

important point that although qualitatively a certain amount of moisture may be absorbed, yet quantitatively the amount is too small to do any harm. I am doubtful also whether the author's results are the best that can be obtained with impregnated windings when using modern flexible insulating compounds. I am also at a loss to understand why in his experiments on oil Mr. Evershed used cylinder oil. The results would have been more useful if good transformer oil had been used. The so-called "dry" oil of Fig. 21 was probably not really dry or I should have expected a larger change in the resistance. Tobey² has shown that 0.03 per cent, i.e. 5 or 6 drops of water per quart of oil, reduces the dielectric strength by 25 per cent. The dielectric strength is, however, not proportional to the insulation resistance. In fact the latter is of very little use in the investigation of the electrical properties of oil. These are much better studied from the point of view of dielectric strength against electrical breakdown.

I am not able to agree with Mr. Evershed's statement on page 64 that on evaporation the electrolytic ions generally remain behind. If the water be pure the conductivity is due to the electrolytic dissociation of the water itself into the ions of hydrogen, hydroxyl, and oxygen. These are in a state of chemical equilibrium with the water itself and evaporation does not affect the conductivity. If, however, there are dissolved salts in solution the evaporation of the water naturally increases the concentration of what remains and this will cause the conductivity to increase. I cannot but admire the author's resolution of the water into resistance water and dormant water. This conception will doubtless prove exceedingly fertile.

In the footnote on page 51 the author somewhat deprecates the application of flash tests to electrical apparatus. I have, however, to join issue with him on this point. In fact I have no great belief, as far as electrical machinery and apparatus are concerned—I am not speaking of cables—in specifications which call for an insulation resistance of a certain number of megohms. What the purchaser requires is an easily applied test which will ensure him a reasonable margin of safety against breakdown. In my experience a specification of insulation resistance will not give this. The only thing which will do this is to require the application of a test pressure for a more or less lengthy period. I think I can detect Mr. Evershed's influence in some of the specifications issued by the Engineering Standards Committee, especially those for instruments and meters, where standard requirements for insulation resistance are given which in my opinion are useless in ensuring that the purchaser will get a satisfactory article from the point of view of immunity from insulation trouble. I quite agree that on high-voltage machines too high a test pressure is not desirable and is apt to damage the dielectric. Nevertheless, in principle, the high-pressure test is the only reliable one. The chief advantage of the measurement of insulation resistance is that it enables us to discover bad places in the insulation, and by studying the variation in the insulation resistance from day to day faults that are developing can be localized. It is not possible, however, at any rate in the present state of the art, to guarantee on the basis of an insulation-resistance test only, that an electrical appliance has a sufficient margin

of safety to stand up against the usual working practical conditions. A pressure test is much more useful in this direction and in my view should never be omitted.

Dr. G. BAXLOW: Another model of an absorbent insulator could be made by closely packing granules of a non-absorbent and highly insulating material, e.g., sand. The leakage paths in this case might be expected to represent the conditions in a porous material much more nearly than the parallel tube model used by the author. Measurements of the resistance of porous materials at temperatures low enough to freeze the condensed moisture might be of interest. In order to produce such solidification within the pores one would probably have to lower the temperature a long way below the normal freezing-point.

Mr. A. R. EVERSHED: The author has described some very interesting investigations in connection with the objectionable change in insulation resistance of fibrous or moisture-retaining materials when tested with different applied pressures, but it is a little difficult to combine these new theories with the facts already known. Previous investigations regarding the changes in insulation resistance have been principally devoted to study of the changes with temperature. A paper was read before the American Institute of Electrical Engineers several years ago describing a research upon the variation in insulation resistance of fibrous materials with varying temperatures. The suggestion was made that the entrapped moisture exists at the lower temperatures largely in the form of disconnected particles, and that as the temperature is increased these particles split up into smaller particles, increasing the number of continuous chains through the thickness of the material, causing greater leakage, and accounting for the lower insulation resistance. Other investigations have shown that when a material of this class is subjected to a high-potential stress heating is produced, and this heating in turn by lowering the insulation resistance increases the leakage losses and causes still further heating. Disruptive breakdowns occur if the temperature is allowed to exceed a critical value for the material and potential gradient in question. If the material is kept cool by artificial means, higher pressures are endured without breakdown. A slot tube of cemented paper or similar fibrous material will have a certain breakdown value when tested on a tinfoil-covered wooden mandril, but will endure higher pressure without breakdown if a solid steel mandril is substituted. On the other hand, if the temperature is artificially raised, the potential gradient sufficient to cause breakdown is reduced. Again, if a mica barrier is placed so as to interrupt the leakage losses which cause the cumulative heating, much higher potentials can be endured without breakdown. This subject was discussed in Mr. Rayner's paper on "High-voltage tests and energy losses in insulating materials." Perhaps Mr. Evershed would kindly indicate how far it would be necessary to modify his theory in order to take into account the effects of temperature. I should also like to ask Mr. Evershed if he has made any tests upon Bakelite or upon fibrous material treated with it. Insulation made up with this material shows a much smaller decrease in insulation resistance with an increase in temperature.

Dr. M. L. KAHN: Mr. Evershed's paper is of great importance as it contains definite statements with regard to the

* *Transactions of the American Institute of Electrical Engineers*, vol. 29, p. 1198, 1910.

* *Journal I.E.E.*, vol. 49, p. 3, 1912.

insulation resistance of electrical apparatus. I have always felt that this particular feature of electrical apparatus has not been investigated as much as it deserves, especially as the insulation resistance is often one of the qualities mentioned in specifications for electrical apparatus. It seems that there are two conclusions which may be drawn from Mr. Evershed's investigations. The first is that it is absolutely useless to specify any value of insulation resistance without stating the voltage at which the measurement is to be made. Although this has been recognized by many engineers, the majority of the specifications issued still omit to state the voltage. As the instruments by which the insulation resistance is measured are usually made to give 500 volts, and as it appears from Mr. Evershed's paper that in the neighbourhood of this particular voltage the insulation resistance is comparatively constant, I should like to propose that this voltage be adopted as a standard for testing insulation resistance, if this is to be specified at all. As the author has made all his tests up to this pressure, it appears that he also regards this particular voltage as a standard for insulation-resistance tests. The second point which is clearly brought out by this paper (although it has of course been well known to most electrical engineers) is that the insulation resistance of electrical apparatus is by no means constant, even if taken at a given voltage. The variations shown in Mr. Evershed's paper, although they are very remarkable, are often exceeded in electrical apparatus. The insulation resistance of such apparatus can sometimes be increased 10 times or more by a simple drying process. As the paper clearly shows that the insulation resistance entirely depends on the amount of moisture suspended in the insulating material, and as this is something foreign to the actual apparatus and can be altered without altering the apparatus in any other respect, it is quite clear that the insulation resistance is not an intrinsic feature of the apparatus and should therefore be entirely abolished from all specifications. The insulating properties of such apparatus can always be clearly proved by the usual pressure tests. Insulation tests will of course always be very useful to determine the state of the insulation of any apparatus at a particular time, or to show if the apparatus can be subjected to flash tests after it has, for example, been standing about for some time.

Mr. E. O. TURNER: There seems to exist at present great difficulty in judging the relative merits of similar pieces of insulating material tested by different experimenters. Apparently the puncture test is the only one which gives at all consistent results. On page 61 the author points out that if a test-piece is carried through a standard course of vacuum baking and varnishing, its insulation resistance after some time settles down to about a fairly steady value. I should like to ask the author whether the succeeding variation of resistance can be represented as at all a definite function of the humidity of the air. Were this the case the insulation resistance, dew-point, and temperature might be measured simultaneously at a fixed voltage. A correction could subsequently be made to a chosen standard of humidity. It would be of interest to know if the author can hold out any hope of forming a basis for comparison of results obtained in this way for test-pieces of uniform size. Referring to Fig. 1, it seems possible that at the final part of the curve, near the breakdown point, there

might be an appreciable rise of temperature in the moisture channels—if these still persist—due to the concentration of the energy loss in a minute volume. In this case the extremely high negative temperature coefficient of water might account for the rapid drop in the curve. As published figures on this subject are scanty I have drawn up the following table, giving resistances in megohms per centimetre cube, to show how large the variation is.

Temperature in degrees C.	15	20	40	60
Pure water (containing no CO ₂)	37	25	8.5	5.0
Distilled water	0.45	0.24	0.11	0.06
Tap water	0.014	0.012	0.008	0.005

A local rise of temperature before puncture has been noticed, particularly in high-voltage alternating-current tests. It seems possible that with low voltages also a small effect of the same kind might be observed.

Mr. W. C. S. PHILLIPS: So far the results of Mr. Evershed's work seem to show that a good non-absorbent insulator obeys Ohm's law. In the case of absorbent insulators, the current is not proportional to the voltage, the irregularity being due to the presence of water—a substance which does obey Ohm's law within certain limits. In order to explain this apparent paradox the author suggests that the exact mechanism of conduction is by electric endosmose. I should like to know if the author has conducted any experiments on paraffin wax, as I consider it desirable that his theory should be tested on substances which can be melted in vacuo. Some recent work by Swann* may be of interest in connection with this paper. He has worked at a potential gradient of 50,000 volts per cm. The method adopted by him was to enclose the paraffin wax between two metal plates AB (see Fig. A)

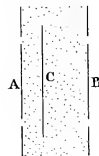

FIG. A.

which were surrounded by guard rings. The third plate C was completely immersed in the paraffin wax, which was heated for some time to 120° C in vacuo and then allowed to cool. The plate C was nearer to A than to B. The method of experiment consisted in earthing all three plates and guard rings, removing the earth connection and then momentarily charging C to a high potential. This was done by passing a wire from a high-potential battery to the edge of the disc C through a hole made in the wax. On removing this wire the hole was filled up by locally melting the wax with a hot wire. Surface leakage was

* *Philosophical Magazine*, vol. 26, p. 678, 1913.

thus completely eliminated. The rate of motion of the needle of an electrometer connected in turn to A and B was then noted, and it was found that when C was positively charged, the plate A acquired a positive charge and B a negative charge. If the substance between the plates obeys Ohm's law there should be no change in potential of either A or B. This was shown to be the case where the wax was replaced by paraffin oil. Thus the electrometer only shows that portion of the current which does not obey Ohm's law, and in some of his experiments Swann calculates that the current so observed is about 60 times the current calculated by means of Ohm's law. The total current taken by the wax is some function of $\frac{dV}{dx}$ the slope

of potential. I should like to ask Mr. Evershed if he considers these anomalous results are to be explained by his theory.

Mr. F. FORREST: The effect of temperature upon the insulation resistance of non-absorbent insulators such as rubber and gutta-percha is very pronounced, and with both materials a rise in temperature is immediately accompanied by a serious fall in the insulation resistance. The author does not deal with this important point in his paper, and it would be interesting to have his views on this matter. Gutta-percha cable when submitted to an external pressure (as occurs when it is laid at the bottom of the sea) shows a marked increase in insulation resistance, whereas the samples of paper tested by the author (see Figs. 14 and 15) showed an equally marked decrease with an increase of pressure. Can the author explain this difference in behaviour? The only really satisfactory method of testing the insulation to earth of an electrical machine is by means of a flash test carefully carried out at a pressure several times greater than the normal working voltage to earth. This flash test will show up weaknesses in the insulation to earth which could not be discovered by any other method.

Mr. S. EVERSHED (*in reply*): Dr. Garrard suggests that the moisture curve might possibly be explained by supposing the absorbent insulator to act like a number of electrolytic cells in series. This hypothesis occurred to me at an early stage of the research. It was the subject of a long series of experiments which all went to show that the curve was not to be explained in that way. To mention only one of the stumbling-blocks we encountered: If the curve connecting applied voltage with the apparent resistance V/I of any number of electrolytic cells in series is investigated, it will be found that R_0/R_{∞} varies from infinity at the beginning of the curve to unity when the applied voltage is enough to swamp the back E.M.F. This follows at once from the equation for the current in a cell, and is independent of the value assigned to the voltage ratio n . But the most marked feature of the moisture curve is that when once the applied voltage exceeds the back E.M.F. of a single cell by a few volts, the ratio R_0/R_{∞} settles down to a nearly constant value, which it retains over a wide range of voltage. In other words the cell curve and the moisture curve follow entirely different laws. Quite apart from experiment, however, the hypo-

thesis of cells in series breaks down the moment we ask ourselves where and what are the electrodes of the supposed cells? As regards the water-in-oil experiments, my only object was to ascertain whether in that case water gave a typical moisture curve or not. The fact that the cylinder oil already contained some water did not prevent the experiments from answering the question with a decided negative. Dr. Garrard and I do not really disagree about the effect of evaporation on the conductivity of electrolytes: all that the statement in the paper means is that in most cases it is dissolved salts which provide the majority of the ions.

If Mr. Everest will refer to the moisture curves given in the paper, and reckon the electrical power spent in heating the various things that were tested, he will find that in no instance did the power exceed a small fraction of one watt. The fact is that throughout the whole of the moisture curve, right up to the point of inflexion, heating is quite inappreciable. It is only when we come to the second part of the complete characteristic curve and the breakdown point is rather closely approached, that heating becomes a serious factor.

Dr. Kahn suggests that we should standardize the testing pressure. Surely the only reasonable standard to adopt is one based on the voltage at which the apparatus under test is intended to work. There is no particular virtue in 500 volts, but the investigation of the moisture curve has been carried out with that pressure as a maximum, simply because it happened to be the ordinary limit of our testing battery. I am providing a pressure of 10,000, and possibly 20,000 volts (continuous current) for the investigation of the breakdown part of the complete curve.

Replying to Mr. Turner, an absorbent insulator is an excellent hygrometer, but the cost of the necessary testing apparatus is a serious obstacle to the adoption of this method of determining the humidity of the air.

I was much interested in Mr. Phillips's account of Swann's experiments on the resistance of paraffin wax. It is difficult to believe that there were any cracks in the wax, and still more hard to believe that there was any water present to find its way into the cracks if they existed. Hence it is hardly likely that the decrease in resistance with increase in pressure was caused by endosmosis.

Several speakers have defended the flash test on the score of utility. I have not denied the utility of a pressure test; on the contrary I regard high-pressure tests as essential to the maker of electrical plant. What I deprecate is the blind way in which such tests are generally conducted. What should we think of the civil engineer who, having built a steel bridge for a railway, ran on it as many locomotives as he could collect and then shut his eyes? The engineer who knows what he is about applies the load, measures the deflection, and notes the set when the load is removed. It is time we electrical engineers put our pressure tests on the same basis. To do that involves nothing more than the use of a high-tension continuous-current dynamo, with some kind of current indicator or resistance indicator to give warning of latent defects in the insulation under test.

WESTERN LOCAL SECTION, 1ST DECEMBER, 1913.

Mr. H. F. PROCTOR: From what the author has said it seems to me that in adopting a pressure test it is reasonable that such pressure test should be applied for a short period only, but I also think it desirable that all high-pressure tests should be applied after the normal working pressure has been applied for almost an unlimited period of time. The endomose effect is thus obtained under working conditions by applying the normal pressure and maintaining it, after which the high pressure should be applied with a view to ascertaining whether a breakdown results by adding the extra pressure. I should like to ask the author whether any experiments have been made to ascertain results with tests carried out by alternating current? Of course, as the author has said, continuous current should always be used for such tests, but it seems to me quite conceivable that alternating current may give, and from the paper does give, at any rate to a certain extent, the endomose effect, where I presume the capillaries are very small. I think it would be interesting to have some further information upon the matter, because so many of us, of course, deal with alternating current alone. I should also like to ask with regard to the oil used for transformer work. A good deal has been said about the use of oil for saturating materials, and varnish, and the results obtained, but I think it would be interesting if the author could tell us anything about oil in its bulk form as used for transformer purposes. Have any results been obtained as to absorption of water by oil, also are there any ready means for testing oils to see whether water is present or to see whether oil is of such a nature that it is liable to absorb water? Some time ago I had occasion to carry out an experiment in connection with the introduction of iodine into the human system, and I rendered the process visible by passing the iodine through gelatine. The transference of the iodine was very evident. I take it that the introduction of iodine into the system by electrical means (Kataphoresis) is practically the same thing as endomose, and it appears to me just possible that experiments may have been carried out by the author as regards the transmission of water through oils. I think that information on this point would be a matter of very great interest to those of us who have to use transformers.

Professor D. ROBERTSON: Mr. Evershed's conception regarding the processes which take place inside a moist material, aided as it is by his ingenious model, must be of the greatest value to those who have to study the subject closely. The constancy of the ratio in his characteristic curves is very remarkable, as is also its agreement with that determined for his capillary-tube model. Attention might be drawn to the fact that the value of 2.15, which is given as the average deduced from Mr. Rayner's tests, corresponds very closely with the simple law that the insulation resistance varies inversely as the cube root of the testing voltage. In connection with Figs. 8 and 9, it does not seem quite justifiable to term the whole of the variable part of the current "charging current." If the properties of the material did not vary with time, there would of course be a charging current in addition to the leakage current at the moment of switching on, but even with a battery resistance of several megohms a few seconds would suffice to reduce this to a negligible amount. Actu-

ally the material goes on yielding with time, and we have the phenomenon of absorption and residual charge which make the charging current die away much more slowly. Here, at least, the author would seem to assume that all the change is to be ascribed to the capacity effect and none to the resistance, although in his experiments with his model he both observed and explained changes in resistance with time as well as with voltage. Of course what he here terms the "leakage current" does represent the actual leakage that would be found with continuous-current working, but it would probably have no more meaning for alternating-current apparatus than the usual "after one minute's electrification." The author's explanation of the action of his model is beautifully simple, but almost too good to be true. The action of a potential gradient on the positively charged water would be to exert a force on the whole length of the film, and it is not evident why that should produce any effects such as those indicated in Fig. 27. With a uniform field the force would be the same all along the film, and would produce a bodily movement without any accumulation at some particular place. To account for the thickening of the film in this way it would be necessary to assume that the potential gradient is concentrated at the positive end, or that the friction is less there than elsewhere. An increase of pressure of the main body of water at the positive end would not force the water into the film, but would flatten the end of the bubble, contrary to the observations. The author's theory gives a somewhat doubtful explanation of the film effect, and none of the end effect. A complete explanation would have to deal with the air-water surface as well as with the glass-water one, and would have to take account of the changes produced by electrification on the effective amount of the surface tension. An increase of the curvature at one end, as observed at the positive end A, indicates the occurrence of one or both of two things, viz.: (1) An increase of the excess pressure of the inside over the outside of the air bubble; (2) a diminution of the surface tension. A flattening of the end, as at the negative end B, indicates the reverse of these changes. The first suggestion would require a negative volume change in the air bubble or in the main body of the water, or both, in order to produce the right pressure changes, and it offers difficulties in accounting for the entrance of water into the film at a place where the pressure is reduced relatively to the inside of the air bubble. Surface tension always tends to pull the surface into as small an area as possible, at least when the surface separates a liquid and a gas. An electric charge on the surface, on the contrary, tries to repel it out as far as possible, and that action is the same whatever the sign of the electrification. Consequently the observed surface tension is practically always less than the real surface tension, because separating surfaces are nearly always electrified, and materials in contact are at different potentials when they are in equilibrium. If, as in a capillary electrometer, we make this potential difference differ from its normal value, the effective surface tension will be decreased or increased according as we have increased or decreased the opposing electrical action. In our model we may

Professor
Robertson.

PROCTOR

Professor
Robertson

suppose that the battery makes the water at the positive end more positive than normal to the air inside, and at the other end less positive. If, then, the water is normally positive to the air, in accordance with the author's statement on page 68, the application of the battery will increase the electrification of the positive surface of the air bubble and decrease that of the other end. This would reduce the effective surface tension at the former, and increase that at the latter, and the result would be exactly the changes of curvature which the author describes. We have still to account for the water forcing its way into the film when the potential difference is applied. For this purpose we must consider the outer surface of the film. The surface tension there tends to draw the water over the surface, but the tension of the air-water surface inside, in its endeavour to take the spherical surface of minimum area, tries to squeeze the film out. The thickness of the film is determined by the equilibrium of these two actions. Consequently, the reduction of the effective tension between the water and air at the positive end of the air bubble enables the external tension to force more water into that end of the film when the battery is switched on. At the other end we should expect some of the film to be squeezed out, which is neither contrary to what the author says, nor supported by his experiment. We may reasonably suppose that the electrical conditions change gradually from one end of the bubble to the other, and that they will also change with time as the film grows. In fact, the growth of the film will have the effect of concentrating the potential difference on the thin end, thus carrying with it the region of reduced surface tension, giving the "wave-front" which the author mentions. It is not by any means to be expected that the expulsion of water from the negative end of the film, if it does take place in accordance with the theory here given, will amount to as much as the water taken in at the other end, for it is known that surface tension is greatly modified when the films are very thin. The alterations produced by electrification on the surface tension of the air-water surface are thus sufficient to account completely for the way in which the bubble and film behave, and they do so much more satisfactorily than the theory propounded in the paper. It must not be forgotten, however, that the real value of Mr. Evershed's model in assisting us to understand the actions in a moist insulator does not depend upon the correctness of his own particular way of explaining why it acts as it does. The appendix on insulation valves is to be commended as a clear exposition of the cause of polarity and valve effects in moist insulators.

Mr. W. A. CHAMEN : This is a most valuable paper but difficult to discuss. One naturally thinks of the effect of moisture in alternators. I suppose that the ideas we have hitherto held that porous insulators if kept at a high temperature, are their nearly always are in electrical machinery, are quite safe for working, are not wrong. The information obtainable up to last June was to the effect that we had nothing whatever to fear from the use of wet-air filtration. I suppose we are still right in assuming that while the temperature of the porous insulator is kept fairly high, say to 200° Fahr., we have nothing to fear from the absorption of moisture. I rather gather that the only insulators which are not porous, so far as the author's experiments have gone, are india-rubber,

gutta-percha, and perhaps one or two substances of that nature. We have been accustomed to look upon porcelain perhaps too much as a non-absorptive material, particularly if well glazed. The author's experiments with porcelain are therefore most instructive. With regard to the last part of the paper, I am reminded of a very peculiar occurrence in Glasgow some years ago. A continuous-current triple-concentric cable had broken down. The positive conductor was in the centre, then came the negative conductor, and the neutral was outside next to the sheathing but of course insulated from it. All three conductors were disconnected from the source of supply and a test was made by connecting through a lamp any one of the "dead" conductors in the first case with the positive pole of the supply; the lamp immediately glowed to full brightness but rapidly dropped down to a dull red. The connection was then suddenly reversed so as to connect the "dead" conductor with the negative pole of the supply; the lamp at once glowed again with full brilliancy and then began dropping down to dull red. This test was repeated several times, always with the same result. The fault was found to be in the neck of a cast-iron joint-box, where the lead sheath of the cable was taken in. It was intended of course to make a really substantial metallic bond between the cast-iron box and the lead sheathing of the cable, for the purpose of conducting back any currents that might arise through breakdown. The jointer, however, had wrapped around the lead, where it passed through the gland of the box, a most elaborate system of mica sheets, which of course left capillary passages right through the gland from the damp earth outside to the interior of the box. I have always thought it was moisture getting in between the sheets of mica which gave us that extraordinary effect, but have never found time to try experiments to prove it. I do not know whether what the author has told us about his porcelain test is quite a parallel to what I observed. I think his case differs from mine because the insulation of the porcelain appears to be always high in the one direction and low in the other, while I found low insulation in each direction to start with, which insulation immediately rose.

Mr. A. N. MOORE : Last summer I made some careful investigations of wet-air filtration, and also discussed the subject with engineers who had already adopted it. I learnt that in one case where a wet-air filter had been installed the insulation resistance had immediately decreased, but it decreased only to a certain point, and for some nine months afterwards; the humidity being kept constant, the insulation resistance did not vary under ordinary conditions. Whether there is a limit to the amount of moisture absorbed by the insulating material in the case of a highly insulated high-tension machine or of any ordinary generator, and whether the presence of moisture really matters, provided the quality of insulating material is such as to render any breakdown unlikely, assuming the factor of safety is not exceeded, and that the limit in the amount of moisture present necessary to bring about a breakdown has not been reached, are questions which naturally occur to one.

Mr. J. L. WILSON : In connection with the bottom part of the curve in Fig. 1 where the material is approaching the breakdown point, it would be interesting to know what kind of recovery the material makes when that point is

reached. Information regarding the behaviour at that point will be of the greatest practical interest when the author has concluded his investigations. With regard to the "valve effect" which the author mentions, most of us know of this phenomenon and when making tests it is usual to take two readings with the terminal connections reversed. It is surprising to find such a large difference, which is much greater than any I have experienced.

Mr. S. F. WALKER: I am in full agreement with the author's remarks in the first part of his paper, and I should like to mention that what he has given us in such detail in the numerous curves that are distributed throughout the paper, practical electrical engineers have known, though not in such detail, for a very long time; indeed, since the early days of electric light. I remember at a meeting of what was I think then still "The Society of Telegraph Engineers and Electricians" there was a discussion upon the insulation of cables. I have forgotten the exact subject of the paper, but I remember that I opened the discussion by pointing out that the practice which had been common up till then and which was advocated in all the text-books, of measuring insulation resistance with a battery of comparatively low pressure, was wrong. I pointed out that if accurate results were required, results that would be of any use in laying out plant, the insulation must be tested with at least the pressure that was to be employed when the cables, etc., were in use. To my surprise I was followed by a number of practical men, telegraph engineers and others, who had had to deal with the same problems, and who had found the same results.

I am also in hearty agreement with Mr. Evershed in condemning "blind tests of breakdown voltage." I have always considered that while it is wise to know all about a cable, by testing a representative portion of it to the very utmost, and breaking it down, it is very unwise to subject to a very much higher pressure than the working voltage a cable which has subsequently to be employed for transmitting power. It has always appeared to me that it is impossible to prevent the insulation being strained, thereby decreasing the final value of the dielectric as an insulator. What the author has also worked out in such detail, viz. the effect of moisture, is what we were all aware of, though we had not the figures before us: we did not know anything about the curve that he has given, and we merely knew that the presence of moisture lowered the resistance of any insulator, and that the more moisture we allowed to get in the lower was the insulation resistance. I do not think many of us knew that the moisture was also subject to the effect of the higher pressure, although most of us were aware that with higher pressure we got a lower insulation resistance. The work which Mr. Evershed has done and the constants that he has worked out will be of great value.

One of the greatest difficulties with which electrical engineers have to contend, is the expansion and contraction that take place with variations in temperature. Unfortunately, we cannot avoid variations in temperature; and these expansions and contractions will always cause the openings for moisture that the author has discovered. His experiments remind me again of my experience in the very early days of the use of electricity in mines. I remember the trouble which I had in keeping moisture from moving contacts. It was not possible to lead wires or cables through glands, so closely embracing them that moisture

would not penetrate; and it was only possible by providing Mr. Walker very wide flanges to enclose contacts so that moisture did not reach them easily. Water vapour, and water itself, have very aggravating tricks. For instance, a crack in a casting that is practically invisible to the eye is quite sufficient to allow water to find its way through to contacts which the casting is intended to protect. What I used to call the "capillary dodge" is made use of. The water assumes the form of vapour, passes through the crack in that condition, and condenses on the inside. I found that the only way to cheat moisture was to give it a very long path, by having very wide flanges as carefully machined as possible. I suggest that some of the peculiar phenomena which Mr. Evershed has found in the tests given in Table I are due to what I may term the interaction of air and water. My work in connection with refrigeration, heating, and ventilating, together with a close study of the waywardness of steam, have shown me some of the tricks which air and vapour together will perform. For instance; air has a capacity for absorbing water vapour, which capacity increases very rapidly with the temperature; and consequently it may easily happen that a small body of air is carrying a comparatively large quantity of water, a certain portion of which it will deposit immediately its temperature falls. On the other hand, water evaporates at all temperatures, and whether it will evaporate or not depends upon, as I think is well known, the difference in the tension of the vapour issuing from the water and that present in the air. It will be found, I think, that a similar set of phenomena take place with the vapour of oil and water, and air; I suggest that further experiments should be carried out on those lines. All mineral oils, it will be remembered, are more or less composite bodies and will give off vapour at different temperatures. In the conditions under which electrical apparatus has to work, it is never certain when the temperature will rise and when vapour will be given off. Hence it appears to me that what may be termed interaction may take place between the vapour of the oil used for insulation, the water vapour, and air. If a fall of temperature follows a rise of temperature it may easily happen that there is a space left, into which air may penetrate carrying water. I also suggest that the peculiar action which the author has found, that only a small portion of the water present in the test pad of filter-paper upon which he experimented takes part in varying the electrical resistance, is due to the action of the air. I suggest that interaction is going on there, between the air and the water vapour.

There is another very interesting series of phenomena in connection with liquids, which the modern science of chemical physics has investigated. The majority of liquids will dissolve practically all gases; and when a gas is dissolved in a liquid it gives up its latent heat of gasification, the temperature of the solution being raised in consequence. Further, the ability of any liquid to dissolve any gas decreases fairly rapidly as the temperature rises. This fact is taken advantage of in one of the methods employed in refrigeration. It appears to me again that the oil in the liquid state which is present in paper, or as the insulation for transformers, for instance, may alternately dissolve air and water vapour and drive them out, according as the temperature falls or rises. The whole matter is very complicated; it demands a large

amount of study and a great deal of careful experimenting to investigate it thoroughly, and I for one heartily welcome the work which Mr. Evershed has done. I hope that he will continue it.

I have for a long time wanted to carry out an extensive series of experiments upon cables. My idea has been to obtain a number of lengths of representative cables and to submit them to varying pressures; to test them periodically, and at stated intervals to strip portions of them. I think that what we want to know is what is taking place inside cables subjected to different pressures, both continuous and alternating. There is one other point which is worth consideration and which I think the author has not mentioned, viz, the osmotic action of a continuous current. I think it has been found that the action is present even with alternating currents, owing to what may be termed the resultant current. Osmotic action must take place wherever currents are passing, and it will introduce still another factor into the equation.

Mr. E. B. VIGNOLES (*in reply*): I am placed in rather an unfortunate position in having to reply to the discussion which has taken place, not being myself the author of the paper. It deals with a very complicated subject, and the matter is almost as new to me as to members present. Anything I now say therefore must be taken rather as my own personal view than as being authoritative answers to the questions raised.

Mr. Proctor put one or two points. First, whether the resistance of dielectrics was usually constant. I think the curves in the paper will show that as far as Mr. Evershed's observations go, dielectrics, when there is no moisture in them, do behave in that way, that is to say there is no fall of resistance with increase of pressure. Mr. Proctor further suggested that high-pressure tests should only be applied for a short time and after the material has been subjected for a long period to normal pressure. Mr. Evershed's view with regard to high-pressure tests is that if such tests must be made then it is most desirable that there should be in the circuit during their application some means of knowing what is the result of what is being done. Mr. Rayner showed in London a method which he had developed for ascertaining that, and it impressed me as being very useful. He subjects the material to an alternating pressure, say 2,500 volts, and in series he has a milli-ampere meter with a battery which has to pass a small continuous current through the insulation material superposed on the alternating current. The alternating current is doing the breaking down of the insulating material, and the continuous current is showing to what extent it is being broken down. He showed us curves obtained by this method, which were extremely interesting, but it appears only applicable to that part of the characteristic curve where the insulation is on the point of breaking down. Mr. Proctor further asked whether tests could not be carried out by means of alternating current. The difficulty is to get an instrument which is sufficiently sensitive. I imagine that is the reason why these experiments have never been carried out with alternating current. The absorption of water in oil is not dealt with in the paper.

I was very much interested in the remarks of Professor

Robertson on the explanation of the phenomena which Mr. Evershed observed under a microscope. I am quite unable to discuss such a complicated matter on the spur of the moment, but no doubt Mr. Evershed will have something to say to it when he comes to write his reply to this discussion. Mr. Chamen alluded to the moisture in absorbent insulators which are kept more or less constantly at a high temperature. It seems to me that if the temperature is above boiling-point of water, it would be impossible to have condensation of moisture. [Mr. Chamen: I suggest about 200 degrees, which would be below boiling-point of water.] If below boiling-point I should say there would be some moisture condensed, but less than at lower temperatures. The phenomena observed by Mr. Chamen on cables were interesting, but I could not follow them in sufficient detail to suggest any explanation. There may have been something in the nature of valve effect there, but I doubt it. It looks more like an effect of capacity.

As to the recovery of resistance of the material on the lower part of the characteristic insulation curve, I think Mr. Wilson's remarks are interesting, and when Mr. Evershed comes to investigate the breakdown part of the curve, recovery no doubt will be one of the phenomena to be taken into account.

Mr. Walker pointed out that the general trend of the phenomena shown by these curves was known. Of course, that was so; Mr. Evershed points that out in his paper. But I do not know that I ever saw the complete curve before. It is quite possible that it has been published, but I have never come across it. Mr. Walker pointed out that years ago the question was under discussion whether the working pressure ought to be used in making tests of insulation. That is quite familiar to me. In 1889 Mr. Evershed introduced a testing set for that very reason, namely, that he realized that the tests must be made at the working pressure. He therefore introduced means by which that could be done. I was pleased to note that Mr. Walker expressed approval of Mr. Evershed's condemnation of blind high-pressure tests. It seems rather brutal to subject the insulation to a strain which it may not be called on to bear, unless by so doing it is possible to diagnose what, if anything, is wrong with the insulation. It is quite possible that means may be devised for making high-pressure tests really useful, but I believe it is a fact that at present there is no instrument which can give us such information regarding the result of the alternating-current high-pressure or "flash" test as to justify it from the scientific point of view.

Mr. EVERSHED (*in reply, communicated*): I need only add a few words to what Mr. Vignoles has said, several of the points referred to having already been dealt with in my replies to the discussions in Birmingham, London, and Manchester. Professor Robertson's alternative explanation of the phenomena we have observed in a capillary tube under the microscope, is of course quite new to me, and I confess not a little difficult to grasp. It seems at first sight to add yet another complexity to what Professor Miles Walker has aptly termed the unruly phenomena of insulation resistance.

MANCHESTER LOCAL SECTION, 2ND DECEMBER, 1913.

Mr. B. Wellbourn

Mr. B. WELLBOURN: I have already taken part in the discussion on this paper in London, but there are one or two further points to which I should like to refer. While the results given in the paper belong to the first part of the curve in Fig. 1, the author says that he is making arrangements to investigate the lower or breakdown part of the curve. This matter has attracted a good deal of attention, and I am rather inclined to think that the problem is not very complicated. It seems to me that as the number of megohms decreases, the watts lost in the dielectric heat up the moisture and air and disperse them until a conducting path is formed which allows sufficient current to pass to char the surfaces of the conduction tubes. I would ask Mr. Evershed in his reply to this

method of measuring the insulation resistance of absorbent materials after one minute's electrification. We only regard this as a qualitative test because of limiting factors of time and space. Referring to the footnote on page 51 regarding the flash test, my difficulty is this, I do not see what test we are to substitute in the case of any insulator having absorbent qualities to prove if the particular apparatus will withstand the sudden pressure rises to which all electric circuits are subject. I should like to ask if the author has any practical alternative in his mind to substitute for the flash test.

The tests set out in the following tables have been made to show the differences which exist between good and bad paper-insulated lead-sheathed cables. The continuous-

Mr. B. Wellbourn

Test on 7.17 S.W.G. Low-tension Concentric Cable at 14° C. Good Cable.

98.0	60	67	77	85	88	90	8.9
428.0	40	42	47	50	50	51	5.9

discussion to say what he thinks of this theory unless he prefers not to commit himself at this stage. One great value of this paper is that it gives us a mental picture of what is happening in an absorbent insulator. I now have quite a working conception of the distribution of dormant and conducting moisture, and of the way in which they mingle and again separate under varying electrical conditions. In regard to temperature, the author explained at the Institution that it was not necessary to keep the specimens under uniform temperature by artificial means, because there was no measurable increase due to dielectric losses. I would now further ask if the tests described in the paper were taken at a uniform atmospheric temperature. In regard to testing, the author refers to the usual test-room

current pressure was applied for five minutes and then the cable was allowed to recover completely before the next higher pressure was applied. The readings at 11.7 volts are only approximate because of the small scale deflection of the galvanometer, and are from one conductor to the other one "earthed."

Both these cables stood a pressure test of 4,000 volts (alternating current) for 15 minutes. The "percentage electrification" columns are worthy of study, while the figures for the insulation after 1 minute and the different behaviour of the cables at 428 volts are highly suggestive. A cable showing the characteristics of the second cable should not be used despite its passing the pressure test. It is also very interesting to find how curves of the same

general form can be obtained by raising the temperature of an absorbent insulator either by heat from outside or by applying a high alternating-current pressure. If the insulation is measured every half-hour and the results are plotted, the curve will be of similar shape to those obtained by the author, and the ultimate time of breakdown can be predicted from an inspection of the curve.

Mr. A. P. M. FLEMING: In addition to the exceedingly interesting mental pictures of the conducting process in absorbent dielectrics described by the author, there are two outstanding features in the paper, namely: (1) The fact that in the so-called absorbent dielectrics the insulation resistance is governed almost entirely by the conductivity of a small portion of the absorbed moisture. (2) That the insulation resistance of the dielectric diminishes according to a more or less definite law as the voltage at which it is measured increases. While most of us who have had to deal with the subject of insulation have been generally aware of these characteristics, I think that very few have appreciated their magnitude as clearly as has been set forth in this paper. I have only one criticism to make in connection with the measurements recorded—I can find no mention of the temperature conditions under which the investigations have been carried out. It is possible that the author's familiarity with the importance of temperature in connection with insulation-resistance measurements has led him to assume that everybody equally appreciates its importance. I mention this matter because one often finds engineers making comparative insulation-resistance measurements, especially on machines, quite irrespective of temperature, unaware of the fact that a few degrees' difference in temperature may alter the insulation resistance a hundredfold. I think that probably the cable-makers will have many interesting things to say about the paper itself, since insulation resistance plays an important part in their products. Viewed, however, from the standpoint of the manufacturer and user of electrical machines, I hope that the really good work embodied in this paper will not be misinterpreted to be other than valuable research work which will serve as a stepping-stone to a better knowledge of the properties of dielectrics, and that the paper will not be loaded with more than it is intended to bear. Ten years or more ago, it was usual for buyers of electrical machines to endeavour to safeguard the quality of the insulation employed by specifying a high insulation resistance. Similar machines might be called upon to show a resistance of 20 or 200 megohms according to the ideas of the buyer—who, however, often neglected to specify such refinements as whether the measurement was to be made with the machine hot or cold—and to get such figures the manufacturer had carefully to dry out his machine, often to the point of mechanical disintegration of the insulation. Nowadays, the modern counterpart of that machine would undergo no such treatment, and the insulation resistance, if measured at all, would be found to be probably of the order of a megohm or less, according to the size and voltage of the machine. A machine under these conditions is likely to run just as safely and have a far greater life. Electrical manufacturers and most users have in the meantime realized that the real value of the insulation-resistance measurement is to afford a rough indication of the dryness of the materials and of the cleanliness of exposed surfaces.

The resistance measurement does not detect mechanical flaws, and, moreover, if it were possible to do away with all solid insulation and space the conducting parts away from ground by an air-gap of, say, a few mils, the insulation resistance would be infinitely high, but the machine would fail under normal running voltage. On the other hand, a pressure test does serve to pick out local weaknesses such as mechanical flaws, and in a limited way also indicates the sufficiency and quality of the insulation employed. A far better way of ensuring satisfactory insulation is to insist on a rigid examination of the design, materials, and workmanship employed during the different processes of manufacture, and rely on this rather than on an insulation test. As distinct from cable work, there are in electrical machines so many alternatives, insulation paths, and such a variety of mechanical defects possible, that there appears very little prospect of obtaining an instrument suitable for detecting incipient faults, prior to actual breakdown. Further, if such faults could be detected, it would probably be better in most cases to produce a definite and unmistakable failure by means of a breakdown test, since the repair has to be effected in either case.

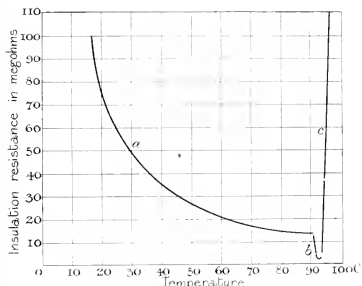

FIG. 15.

In describing the behaviour of the ingenious model insulator, the author is able to show how the process of moisture dispersion goes on. This process is most important, and a number of cases occur in practice which bear out his interpretation of the phenomenon. I have in mind the behaviour of some large 50,000-volt transformers which were dried out prior to pressure testing by circulating hot air through and around the windings. The insulation was measured between the high-tension and the low-tension windings and earth from time to time as the temperature was raised, and the curve shown in Fig. 15 herewith was obtained. The part marked "a" represents a drying period of about 12 hours during which time the temperature was raised from normal to about 95°. The temperature was maintained at about this point for 72 hours, during which time a further marked decrease in insulation resistance as shown by the part "b" of the curve was obtained. At the end of this time the insulation

resistance rose very rapidly to a very high value beyond the range of the measuring instrument. In the first of these stages the moisture begins to be expelled into the main conducting channels; in the second stage this process is continued and completed, and in the third stage the moisture becomes evaporated from the insulation. The insulation consisted of fibrous material impregnated with insulating varnish, and these drying tests were carried out prior to the immersion of the transformer in oil.

From a number of pressure tests that were made, it was found that during the stage represented by "a," the apparatus just failed to meet its specified pressure test. During stage "b," the insulation failed at a considerably lower voltage, and during stage "c" the pressure test was withstood without any trouble whatever. These curves are generally typical of all windings insulated with fibrous material, and in addition to illustrating the dispersion of absorbed moisture show that a certain amount of drying may actually weaken the insulation as regards its ability to withstand a pressure test; it is only when the drying has been carried beyond a certain stage that any benefit is obtained. I should like to know whether the author has tested the absorption of moisture by materials impregnated with varnishes of the linseed-oil base variety, since, with such varnishes, expansion of the base occurs as the solvent is dried out and oxidation proceeds. One would expect in such cases that the absorption would be less marked than with other types of varnish. I should also like to know whether the author has compared such tests with those obtained on materials impregnated with solid bituminous compound, under vacuum. While such compounds have a considerable coefficient of expansion, and moisture absorption is likely to occur due to the "breathing" action which takes place with changes in temperature, my experience has been that such treatment affords greater immunity from moisture absorption than the usual varnish treatment. With reference to the typical conduction curve shown in Fig. 1, I note that the material employed was cotton in its undried state. I venture to think that had a composite dielectric such as is ordinarily employed for the insulation of electrical machines been used, the point of inflexion would have taken place with a potential gradient of the order of say five times greater than that shown, and while the first part of the curve would probably not have changed its shape to any great extent, the ultimate disruption would have occurred at a very much higher voltage, and the first and second portions of the curve would have been joined by a more or less straight and nearly horizontal line, this portion indicating a fairly wide range of potential gradient over which the conduction is approximately stable. A pressure test can be safely applied to such insulation provided it falls within what has been predetermined by experiment to be, the stable portion of the curve.

Professor MILES WALKER: Those engaged on the insulation of electrical machinery are greatly indebted to Mr. Evershed for this work on absorbent insulators, because he has succeeded in reducing to law and order a most unruly set of phenomena. Those who have had to do with fibrous insulators have always regarded the insulation resistance as something so uncertain and changeable that they had given up hoping that any law would apply, and they therefore trusted more to puncture tests, which are

somewhat less uncertain, though still far from being satisfactory. The experiments that relate to the fraction of the moisture in a moist specimen which takes part in the conduction are especially interesting. I, in common with many other people who have observed the serious way in which a microscopical amount of moisture affects insulation resistance, would have thought that if anything the water present had more than its normal conductivity, but it appears that on the contrary only a few millionths of the water present does the work of conduction. One wonders whether the cases calculated by the author would have given the same results if the water used had not been of such a low specific resistance. If, for instance, the pad of blotting-paper had been moistened with pure water of very high specific resistance would not the insulation resistance have fallen by an amount almost as great as in the specimen cited. If so, the calculation as to the amount of water taking part in conduction would be upset. One knows that when moisture is distilled from the atmosphere it greatly lowers the insulation resistance, notwithstanding the fact that it may be very pure water. It would seem as if water spread in thin films on cellulose surfaces sometimes had a higher conductivity than the same thickness of film would have if regarded only as pure water. There is one point that is not explained in the paper. Why should we have an almost constant ratio (about 2) between the resistance at 50 volts and the resistance at 500 volts? Assuming that the theory put forward by the author is correct, we still have an enormous number of variable conditions which one would expect to alter the ratio. Such things as the different nature of the materials, which would affect the surface tension, the different shapes of surfaces, which would affect the amount of endosmosis, the conductivity of the film, and the variation of the potential gradient as a function of the applied voltage. If the author can explain how it is that notwithstanding all these and other variables we might expect to get a constant ratio such as he has shown to exist, he would go a good deal further to establish the theory which from his results seems to have a good deal of probability behind it.

Mr. J. S. PECK: With regard to the various "moisture" curves, I should like to know how long a time elapsed after the voltage was applied until the resistance measurement was taken, as I understand from Mr. Welbourn that if a certain voltage is maintained on a dielectric the insulation resistance decreases with time along a curve exactly similar to those shown in the paper. Does this apply only when a certain critical voltage is reached, or does it apply for any voltage? If it applies for any voltage, I do not see how the curves given in the paper can be determined unless a very great time has been allowed to elapse between the different points in the curves. As to Fig. 1, I should like to know if, after the critical point in the curve has been passed and the voltage is maintained constant, the insulation resistance gradually drops to zero. As to the "harbaric" flash test which has been referred to, the Megger is often used to show whether insulation is in proper condition before subjecting it to this test. We know, for instance, in any line of machines that if the insulation resistance is much below a certain average value the insulation is in bad condition, and it will not be safe to test it under those conditions; we then use some method of

Peck. cleaning the surface or drying out the insulation to make as sure as we can that the insulation is in a sound condition before applying the flash test. In my opinion the greatest value of the paper lies in the clear mental picture which the author has given of the action which goes on in a dielectric under stress. To me, and I think to the majority of engineers, a mental picture is of far more value than a mathematical formula.

Mr. C. J. BEAVER: I think it is clear that the characteristic curve of cotton is also characteristic of all absorbent materials that are capable of holding water in an interconnected cellular structure. The author has dealt fully with the first part of the curve in his paper, and promises future investigation of the third or breakdown part of the curve. I think that the second part of the curve depends largely for its length and angle on whether all the moisture has been driven out of the material or otherwise put out of action. In the presence of moisture, what happens during this part of the curve is that the moisture becomes electrolysed, and the electrolytic products formed will tend to produce paths of comparatively low resistance through which current will pass until the conditions merge into the third part of the curve by incipient charring. A great deal depends on the amount of moisture present. If moisture is absent, breakdown can only be caused by dielectric stress. To take the other extreme, a dielectric which is sodden with water is extremely difficult to break down under a high-voltage test, because the dielectric behaves like a high-resistance conductor. Several speakers have referred to the flash test, and as there appears to be some confusion of ideas on the subject, I think it is necessary to draw a distinction between the flash test as used by machine and transformer builders, and the high-pressure test as used by cable-makers. A flash test usually consists of a very short application of a very high pressure, whereas the other consists in applying a high pressure for a long time. In cable tests any required amount of "trim" can be provided at the cable ends, and precautions can be taken against the possibility of brush-discharge effects causing breakdowns at the ends. Machine and transformer builders have no such facilities for virtually extending their terminals, and under their testing conditions therefore the time element can only be allowed to enter into their test to a limited extent. The flash test therefore should not be utterly condemned, because it has well-defined uses. For accurate determination of breakdown pressures, however, the time element must be provided for.

The form of curve which is stated in the paper to be characteristic of moisture phenomena applies only to those substances containing water which are of such cellular character that the water can move in the capillary passages. Figs. 21 and 22, which relate to cylinder oil containing moisture and undried oil-impregnated paper respectively, afford a clear demonstration of this point. In the former case we have a homogeneous mixture in which the water though capable of being concentrated electrostatically is not capable of being driven in definite paths. In the latter case the oil has not displaced the moisture in the paper, and the sample therefore behaves like any other substance of cellular structure containing water. The subject of moisture in impregnated paper as used for cable insulation has been mentioned both by the author and one or two other speakers, and I gather that an impression exists that all

moisture is not expelled from the paper in manufacturing paper-insulated cables. In the interests of accuracy this impression really must be corrected. Before impregnation, paper contains a certain percentage of hygroscopic moisture, but its vegetable structure does not contain any constitutional or chemically combined water, i.e. it consists of celluloses, and not cellulose hydrates. The hygroscopic moisture is easily expelled by heating, and the paper is then in a perfectly dry condition physically and chemically. Brittleness is not produced by over-drying, as has been stated, but by over-heating. Perfectly dry impregnated paper is not brittle; in fact, it can be easily demonstrated that its tensile strength and elasticity are appreciably greater after impregnation than before. In conclusion, I think the broad lesson which the author's results have demonstrated is that all absorbent insulators have their limits of application. They would appear to be permissible in cases where the first part of the author's characteristic curve merges into a horizontal line, i.e. where the conditions are such that absorbed moisture can be readily expelled under working conditions, the limit in such cases being the dielectric strength of the material. If the moisture is not expelled we shall get electrolytic effects rapidly leading to breakdown at much lower voltages than would be represented by the dielectric strength of the moisture-free material. The combination of absorbent insulators in series with non-absorbent insulators naturally forms a compromise which for many purposes would be found quite satisfactory.

Mr. W. CRAMP: If there is one thing that stands out in this paper more than another, it is the keen sense of order of magnitude displayed. There is no attempt to drag in last decimal points where results do not sanction such a procedure. This is a lesson which we ought all to take to heart when writing papers which are called scientific or technical. I must differ from Professor Miles Walker on the use of the word "hysteresis." "Hysteresis" means simply "lag," and has intrinsically nothing to do with energy. The loss due to electrical and magnetic hysteresis is an energy loss, and thus the word is sometimes assumed to refer to energy only, without any real justification. Lag, and in particular cyclical lag, is denoted by the word "hysteresis" as a phenomenon. The energy corresponding thereto should not be called hysteresis only, but hysteresis energy, or hysteresis loss. On page 56 the author draws attention to two diagrams, Figs. 8 and 9, and he points out that the "one-minute electrification test" is really no measure of anything at all. It seems to me that the effect of this paragraph will be to change entirely the specified tests of cables or machines now subjected to "one minute's electrification." I would ask the author to suggest in place of the "one minute's electrification" some test giving a more satisfactory indication of the insulation properties. On page 57 the author says "leakage through dielectric rubber is nothing, leakage at the fittings is everything." This is perfectly true under the conditions mentioned in the paragraph, but, in testing a cable, leakage through the rubber is just what should be measured. For when all surface leakage has been got rid of there remains the necessity for a test on the rubber or paper to make sure that particles are not present which may conduct. I agree entirely with what Professor Walker has said regarding the shape of the resistance-pressure curves. It seems

to me that the explanation put forward by Mr. Evershed is ingenious and correct as far as it goes. But it is well known that in capillary tubes the spaces between the dormant masses are filled with vapour of the fluid and that fluid can conduct; in this case there is no reason why conduction should not go on in the vapour as well as along the films.

In considering the insulation of electrical machines the use of enamel suggests itself. It is well known that conductors have been covered with flexible enamel for certain purposes. If the conductor of a dynamo were enamelled before it was otherwise insulated, would it not help very much to solve the moisture problem which the author has put forward? Sometimes insulation can be arranged in such an open way that it is possible to get air currents right through the various layers. In such cases the paper suggests that a better insulation test would be obtained than if the air spaces were filled with non-conducting material. Does the author agree with this? Recently a motor was supplied to me which was supposed to have a temperature rise of 75°F. ; but on test it showed a rise of 94°F. When I objected, the manufacturers pointed out that they knew the motor was to be installed in a damp place and they had designed the machine with this temperature rise to counteract the atmospheric conditions. Such an excuse, though really indefensible, does seem to be suggested by the paper; and it raises a very interesting point, viz. Is insulation when in a condition of high resistance nearer to its breakdown or further from it? If the latter, then a case for a high temperature rise in damp situations is made out.

MR. R. G. CUNLIFFE: The main factors affecting the value of insulation resistance, given in order of importance, are the effect of moisture, the effect of voltage, the effect of polarity, the effect of mechanical pressure, the physical structure of the material, and the extent to which the material absorbs moisture. In many standard cases absorption tests are specified in addition to flash tests and tests of insulation resistance, and in some cases flash tests are carried out with the insulator under mechanical stress. The test results given by the author are all obtained by the application of low electrical pressures, and it would be of interest if results were given for higher pressures, especially for extra-high-tension insulators such as porcelain, mica, etc. No mention is made in the paper of the effect of time. Are the characteristic curves shown in Figs. 2 to 23 obtained after definite time intervals for each application of pressure? If so, what are the intervals, and what is the variation in insulation resistance with time, for a definite constant pressure? If a model insulator be constructed by filling a glass trough with fine sand and placing two metal electrodes at the ends of the trough the resistance is found, ultimately, to increase owing to the moisture being driven from the positive electrode by endosmotic pressure. Fig. C herewith illustrates the case and shows the variations of the potential gradient at all points between the electrodes. The full line represents the gradient at the moment of switching on, and the successive broken lines the shapes taken by the gradient curve as the time of application of the pressure increases. It would appear from the test results and materials used that the author has not caused the moisture in the samples to flow bodily, but that there are reservoirs continually supplying the pipe lines formed by the conducting paths. Probably the conditions are

different for solid bodies and sand or powdered insulators and possibly different again for fibrous bodies where the fibres themselves are not impermeable to moisture. The loop referred to in Fig. 2 as the hysteresis effect certainly represents an interchange of energy, the air bubbles in Fig. 27 being compressed whilst the electrical pressure is applied and expanding when the pressure is removed.

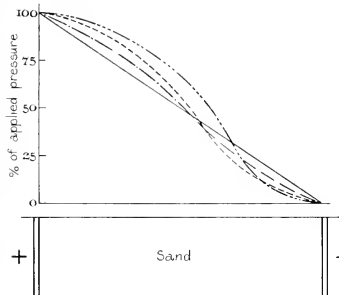

FIG. C.

The relatively immense frictional resistance at the walls of the capillary channel produces the time-lag observed. The constant, the value of which is marked on the curves, is very interesting, and an explanation of the reason for the particular value would be of interest. Possibly if experiments were carried out with very dilute solutions of standard electrolytes forced into the insulating material, other values of the ratio would be obtained which might indicate the reason for the particular values.

MR. G. HUTTON WILSON: This paper is of special interest to Manchester engineers as the words "Manchester," "cotton," and "dampness," are almost synonymous. I have had to dry out a number of armatures and have often found that after stoving all night the insulation resistance is very low when the armature is still hot, but shows no leakage as soon as the armature has cooled down. Probably this is due to surface moisture which evaporates as the hot armature is brought out into the cold air. The author has clearly proved that moisture is always present in windings of every kind, whether varnished or not, and yet the insulation resistance to the frame may be as high as 10 or 20 megohms. Deterioration of the cotton covering of windings, such as field coils and armatures, is generally regarded as the effect of heat and moisture, and I can only call to mind one insulating material which is not deteriorated by heat and moisture. This insulation is aluminium oxide, and instead of causing deterioration, heat and moisture can increase its value, thus having a preserving effect instead of a deteriorating one. Aluminium field coils were referred to in a student's paper last year by Mr. A. T. Robertson. In a footnote to that paper it was stated that the deductions as to aluminium coils were purely theoretical. Aluminium coils, however,

are now a thoroughly proved success and are used very extensively on the Continent, in addition to a number of coils now in service in this country both for tramway and other work.

Mr. H. M. CRELLIN (*communicated*): With reference to the author's theory that the shape or form of the characteristic curves showing the relation between the dielectric resistance and voltage is due to the presence of moisture, I would point out that this apparent decrease of dielectric resistance with increase in testing voltage was shown by Appleyard, in a paper read before the Physical Society,* to be due to imperfect contact between the dielectric and the electrodes. With voltages up to 750, and tinfoil electrodes pressed against the dielectric by rubber discs loaded with 22.3 grammes per sq. cm., he obtained a curve similar to those described by Mr. Evershed as a "typical moisture curve." Increasing the load on the electrodes to 543 grammes per sq. cm. the dielectric resistance was found to be practically constant at all voltages up to 750. Further, on trying mercury electrodes (unloaded) a practically constant resistance was again obtained at all voltages up to 750. Further proof of this explanation is afforded by the results given in Section 6 of Mr. Evershed's paper, in which the author states that several kinds of oils and varnishes were tested, and "in every case Ohm's law was followed, the resistance proving to be a constant quantity." Again, in Section 8 of the paper, two cotton-covered wires after being wound on a porcelain bobbin and impregnated with varnish by the vacuum method were found to have a constant resistance at all voltages—results due, in my opinion, to the more perfect contact obtained between these dielectrics and the electrodes. Then why, it might be asked, does this last test piece (impregnated cotton-covered wires on porcelain) after 9 days' exposure to the air give a "perfectly normal moisture curve"? The key to this is given in the last paragraph of Section 8, viz. expansion and contraction of the windings—causing imperfect contact between the electrodes and the dielectric, or, more probably, crevices in the dielectric, which, by interposing air-gaps give the same effect of apparently lower resistance at the higher voltages. With reference to Fig. 16, it might on first thought seem that contact between the electrodes and the dielectric at such high loadings as 30 to 40 lb. per sq. in. should be perfect enough, but it must be noted that Appleyard found that 543 grammes per sq. cm. (7.73 lb. per sq. in.) was necessary to establish satisfactory contact with far more flexible electrodes than those used by the author. The more rigid copper plates used by the author cannot be regarded as sufficiently flat to exclude all air-gaps from between the electrodes and the dielectric, and thus ensure perfect contact at all points between the surfaces of the dielectric and the electrodes, particularly so in view of the experiments of Dr. Shaw on the Disruptive Voltage of Thin Films, the results of which were given in a paper read before the Physical Society,† in which he found, using the electric micrometer, that such a small air-gap as one micron ($= 1/25,000$ in.) will withstand a pressure of over 200 volts, and that 14 microns of air will withstand nearly 300 volts before breakdown across the gap occurs. Whilst I heartily congratulate the author on the large amount of really useful information which he has

given us as regards actual test results obtained in practice on various windings and apparatus, I disagree with his theory that the apparent decrease of resistance with increase in testing voltage is due to moisture, the phenomena being, as Appleyard puts it, merely a surface effect that can be greatly reduced, if not entirely eliminated, by ensuring perfect contact with the electrodes.

Mr. L. B. ATKINSON (*communicated*): In view of the fundamental importance of "insulation" to electrical engineers, and of the much smaller attention which "insulation" has received than "conduction," the paper by Mr. Evershed is a welcome opportunity for an exchange of views thereon. The paper is of a twofold nature; first, a record of careful experiments with all kinds of materials, extending over several years; and, further, the author has for the first time indicated, and to my mind proved, the cause of the phenomena observed with the majority of commercial insulating materials. His explanation of the variation of insulation resistance with the applied voltage is a permanent addition to our stock of knowledge, and should form the starting-point for improvements in insulation. He must also be congratulated on the clear mental picture of what takes place in insulating materials. It has long been known that insulators were of two classes—homogeneous, such as rubber, wax, and glass; and heterogeneous, such as cotton and air, paper and oil, etc., and though the superiority of the former has been recognized, the requirements of thin layers of flexible materials have led to the wide adoption of the latter class. It may be useful to complete the mental picture the author has given us by considering the structure of such materials and their bearing on the problem. The materials such as cotton, paper, press-pahn, and the like, are composed of natural cellulose matter, the growth of plants, and like all such cellulose matter are the solid matter composed of carbon, silica, etc., forming the framework in which cells of protoplasm have once lived. These cells, depending on the material, are of all sorts of sizes and shapes. In the case of cotton-seed fibres the cells are single filaments, and the envelope forms a tube with a fine hole through it; in the case of wood-fibres the cell coatings are of almost round, hexagonal, or other shape. These cells are very minute. From an approximate measurement I have made under a microscope, a fibre of cotton measures about 1/5,000th part of an inch in diameter, and the central bore averages perhaps one-third of this, or say 1/15,000 in. in diameter, i.e. 0.0016 millimetre.

We speak of these materials as hygroscopic. Now what do we mean by a hygroscopic substance? We mean that at a given temperature when the vapour pressure of water in a space is less than the saturated pressure corresponding to such temperature, water condenses on such a material. To what is this due? Partly, apparently, to the nature of the material, and partly, as Lord Kelvin suggested in 1879, to its form. Thus glass will have a layer of moisture on it at a temperature at which shellac will not. The quantity of water in the normal film of moisture on glass above the condensation temperature has been measured by Mr. W. H. White to be equivalent to a uniform film 0.00001 cm. thick or about twice as thick as the film measured by the author as existing in the tubes of his model. This film has apparently some connection with the chemical attraction of glass for water, all glass being soluble in water. But

Mr. Crellin.

Mr. Atkinson.

† *Ibid.*, vol. 20, p. 289, 1906.

apart from hygroscopic substances of this class which depend on the low vapour pressure of hydrates, there is the hygroscopic property arising from "form." When we have to deal with minute liquid surfaces such as are presented by very fine drops, the vapour pressure on such a surface at a given temperature is higher than that on a plane surface; when we have a concave surface the vapour pressure is lower than that on a plane surface. Consequently if any film of moisture exists in a tube or spherical cavity of small internal radius, further moisture will condense at a temperature at which the air is not saturated with moisture. In a spherical cavity one-millionth of a millimetre in radius, i.e. 1,500,000 mm. in diameter, the vapour pressure at a given temperature is halved; in a tube of the same dimensions the effect is half that of a spherical cavity, and this lowering of vapour pressure is inversely as the diameter. If we take the case common in England of a temperature of 55° F. and an air saturation of 81 per cent, then the saturation vapour pressure being 0.433 in. of mercury, the actual vapour pressure would be 0.349 in. of mercury. In order that the vapour may condense, the surface on which the vapour condenses must have a reduced vapour pressure in the ratio of these numbers, and this, if a spherical cavity, will be 1,100,000 mm., say 4 millionths of an inch. Comparing this with the dimensions given above of the bore of a cotton thread, it is clear that if the hygroscopic property is due to the condensing effect of the small radius of curvature of cavities it is not that of the main cavity. But it may be that this main cavity has openings through the cell wall of smaller dimensions, and that to these the observed effect is due.

The author remarks, "when condensation takes place on the surface of a solid body, it first makes its appearance to us in small detached drops, etc." This may be true of its visibility, but if the substance is one which water wets, then probably this is the secondary effect. A uniform film is first deposited, slight unevennesses cause differences of surface tension, and the film breaks into drops. The case cited by the author of the drops on a spider's web is a case of this kind. It is possible, therefore, that the mechanism of the hygroscopic property and of the formation of plugs and layers of water in the fibres required by Mr. Evershed's theory is as follows: The exceedingly fine perforations of the thread admit moist air, and by their form and dimensions they provide a surface of lower vapour pressure and condense a layer of moisture. This by surface tension is drawn into drops that fill the cross-section of the tube with a plug and leave the film in between the plugs. It may be that the explanation of why we do not succeed in filling the material with oils and varnishes is that these materials are too dense and viscous to enter the capillary bores, and even water would be were it not that it evaporates and enters them in a gaseous form. And the re-appearance of the moisture curve in dried and oil-impregnated materials may be explained by the absorption of moisture by the oil, its transference thereby to the surface of the cellulose material, its re-evaporation there, and its entering in gaseous form and recondensation in the still unfilled capillary openings.

Mr. S. EVERSHED (*in reply*): I agree with Mr. Welbourn that the phenomena of the breakdown part of the characteristic curve are not likely to be so complicated as those

of the moisture curve, but I think it would be rash at the present stage to assert that the rise of temperature, which begins to be appreciable as the curve approaches the breakdown point, is due solely to the power spent by the leakage current in the moisture films. Referring to the curve in Fig. 1 it will be noticed that by the time the region of inflexion is reached the potential gradient is quite high enough to produce a brush discharge from one electrode to the other. Here then is a far more dangerous mode of heating already at work. Mr. Welbourn asks me to suggest some alternative to the pressure test. I have dealt with this question in my replies to the discussions in Birmingham and London, and will only now add that Mr. Welbourn has answered his own question as regards paper-insulated cables. He gives us the tests of two cables both of which passed the pressure test, and both would doubtless have been passed as satisfactory, but for the significant fact that one of them betrayed the presence of too much moisture by giving a typical moisture curve. It is obvious from the figures in Mr. Welbourn's table that at the end of the 5th minute the charging current had not entirely died away, but it was already quite small compared with the true leakage current and the figures for the 5th minute may be plotted as voltage-resistance curves without much error. The tests on the concentric cable are rather discrepant and the ratio R/R_{100} can only be stated as somewhere between 1.1 and 1.35, but the other cable gives an excellent example of a moisture curve with a ratio R/R_{100} of about 3; a useful test, made with our eyes open, and telling us something about these cables which the pressure test failed to disclose. But for all that I would not abandon the pressure test. I only want to improve it.

Mr. Fleming raises the question of temperature as affecting the tests recorded in the paper. Air temperatures were invariably noted; but as a general rule no appreciable change took place during the course of a set of observations on a test-piece, the temperature of the experimental room being fairly uniform. Occasionally a protracted test might begin and end at temperatures differing by three or four degrees, but I have rejected all such tests if there was any likelihood of the temperature change masking the significance of the experiment. Any appreciable rise of temperature due to heating by the leakage current was obviously out of the question; take, for example, the curve given in Fig. 2. At 500 volts V^2/R is just 1/40th of a watt and this was being spent in the armature of a 20-kw. dynamo! As to the various test-pieces, none of them had less than 30 or 40 sq. in. of radiating surface, quite enough to dissipate a small fraction of a watt without any appreciable heating. As regards local heating, rise of temperature in the moisture films, I can only give the conditions in the model insulator. Reckoning from the curve given in Fig. 28, and counting only the area of the external surface of the films (the surface next the glass) the power spent at 500 volts was at the rate of 0.0035 watt per sq. in. Hence the film might possibly have risen in temperature by a fraction of one degree C., if it had not had the glass to cool it.

Replying to Professor Miles Walker the dormant water experiment was originally carried out with distilled water, and gave much the same values for the proportion of resistance water. The result was so unexpected that we

Mr.
Evershed.

1500.

shed.

repeated the experiment with a water of much higher conductivity in order to be sure that it remained substantially unchanged throughout the test. Professor Miles Walker cannot be more astonished than I was at the constancy of the ratio R/R_{orig} . It actually constituted a stumbling-block to rational experiment no matter what change was made in the experimental conditions the moisture curve remained practically the same. However, in the light of the model insulator the difficulty largely disappears. No matter what the absorbent material may be, the same fundamental conditions are always present: the positively charged water, the potential gradient, surface tension, and fluid friction. I feel that if these quantities could all be equated we could construct a rational formula to the moisture curve.

Mr. Peck asked how much time was occupied over the readings. If the insulator was fairly stable, and the capacity current negligible compared with the leakage current, the galvanometer could be read at once. With unstable insulators it is generally advisable to wait a few minutes before observing the current, and where the capacity current is comparatively large it is essential to wait—sometimes for half an hour or more. But even with an insulator as sluggish as the model is in coming to a steady state, quite a good curve may be obtained by taking the readings as quickly as possible, and although the resistance values are considerably higher in consequence, yet the curve has the normal shape. For example, in Fig. 31, curve B was plotted from readings which I took at the Institution as rapidly as the ohmmeter would permit.

I cannot agree with Mr. Cramp that the vapour in the air bubble would have any sensible conductivity at the low potential gradients which generally prevail throughout the greater part of the moisture curve, but of course as the voltage rises there must come a time when the current through the vapour can no longer be neglected.

Mr. Cunliffe's experiment with the moist sand is a good example of the action of endosmose in driving the water away from the positive electrode. With alternating current I think the water should leave both electrodes and collect somewhere in between them. I have not noticed any rise of resistance consequent on a prolonged application of pressure during the tests given in the paper, although I have been on the look-out for it. Probably the test-pieces always held a sufficient quantity of dormant water to supply the stream through the film for a long time, but the point is at present rather obscure.

Mr. Crellin refers, as Mr. Bairsto had already done, to Appleyard's experiments on the contact between an insulator and the electrodes. Of course I accept the facts, but none of the hypotheses which have been put forward by way of explanation carry conviction to my mind. For one thing, the way in which the moisture curve retains its normal curvature throughout a wide range of moisture condition is quite inconsistent with any kind of effect at

the terminals. Mr. Appleyard took a thin sheet of press-pahn and, with solid electrodes making light contact, he traced the voltage-resistance curve. This curve is a typical moisture curve, the ratio R/R_{orig} being about 2.6, and the hysteresis effect is well marked. Finding, as I have since done (see Fig. 16), that pressing the electrodes into firmer contact with the insulator greatly reduced the curvature, Mr. Appleyard next tried the far more perfect contact made by fluid mercury electrodes, and discovered that the resistance of the press-pahn no longer varied with the potential difference. This remarkable experiment not unnaturally suggested that the voltage-resistance curve was the result of something going on at the electrodes, some kind of contact effect; but I am going to suggest another explanation which tallies better with the facts as we now know them. To obtain any flow, any motion, in the moisture films, it is, I believe, essential that the capillary channels should have free access to the air at both ends, a condition which is of course perfectly fulfilled by the little tubes in the model. Plug the tubes, stop the ends of the capillary channels in an absorbent insulator, and I think it would no longer be possible to obtain any motion by the action of endosmose. But if the water cannot flow the films cannot increase their thickness, and hence we should expect the resistance of a plugged channel to remain constant notwithstanding changes in potential difference. Now as we press the electrodes more and more firmly into contact with the porous insulator, we may be simply stopping up the pores one after another, and by means of his mercury electrodes Mr. Appleyard may have plugged the whole of them. Of course this is but a guess; I have not had time to test it by experiment. But if I am right, then we should expect mercury electrodes to have the greatest effect, in stopping the action of endosmose, when they are applied to a thin sheet of insulating material; and to have less and less effect as the insulator was made thicker and air was able to find its way in through the edges or sides of the porous body.

Mr. Atkinson has made a most interesting and helpful contribution to the discussion. In the unavoidable process of compressing my paper into a reasonable length I rather reluctantly cut out a description of the mode in which moisture is deposited in a thin and invisible film which, as it thickens, collects into visible drops. But I am rewarded for my self-denial because Mr. Atkinson has now described what goes on much more fully than I had done and with far more knowledge than I possess.

By the way, I recall that it was in 1888 that my attention was first directed to the subject of insulation testing by Mr. Atkinson and the late Mr. Walter Gooldeen. They suggested that I should devise something by way of improvement on the portable battery and galvanometer which was in general use at that time. Twenty-five years have gone by, and I am still looking for an improved method.

Mr.
Evershed.

THE MAGNETIC LEAKAGE OF SALIENT POLES.

By ROBERT POHL, D.Eng., Member.

(Paper received 22nd October, 1913.)

In the course of an investigation of the regulation of alternators the author found that none of the usual methods of calculating regulation gave consistently reliable results in practice when applied to a range of machines and to various working conditions, and that the discrepancies were largely due to the variability of the leakage factor. The leakage flux is not constant, but increases with increasing load, especially if the latter is inductive, and thus causes an appreciable difference between the flux characteristic at no load and at full load. This subject will be more fully dealt with in a separate publication.

These results led the author to the conclusion that it is necessary to calculate the leakage both at no load and at full load separately, and much more accurately than he had been accustomed to. It was found, however, on looking through text-books and publications dealing with the pre-determination of the leakage factor, that there is need for a fuller mathematical investigation of the problem with

As the basis for our investigation let us consider the design of poles usual in the revolving-field type of alternators. The formulae obtained will be immediately applicable to other classes of salient-pole machines, more particularly continuous-current machines. Fig. 1 represents a diagrammatic view of the flux distribution of such poles. In accordance with the usual definition we shall call the leakage factor σ the ratio of the total flux F_t passing through the base of the pole to the useful flux F_u entering the stator iron and interlinking with the stator winding. F_u may be considered a known quantity. The leakage flux L is the difference between the total flux and the useful flux.

$$\sigma = \frac{F_t}{F_u} = \frac{F_u + L}{F_u} = 1 + \frac{L}{F_u}$$

The unknown quantity L may be divided into two main parts, the shoe leakage L_s and the core leakage L_c . Each

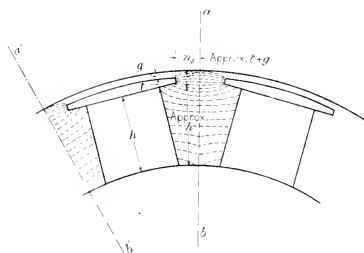

FIG. 1.

a view to obtaining some formulae for practical use in designing offices. Such formulae, in order to be of real utility, should be as simple as possible. At the same time, however, they must give accurate results. These two conditions, considering the complicated character of the leakage paths and the variety of shapes of poles and exciting coils used in practice, are not easily reconciled.

The following is an attempt to supply a fairly comprehensive mathematical investigation leading up to formulae for practical designing work. The formulae, though surprisingly simple, are obtained without any undue compromise, and will be shown to bear the test of experimental verification. Indeed, the writer has employed them with entirely satisfactory results for a variety of electrical machines. Needless to say these calculations do not require to be worked out for every machine passing through a manufacturer's works, but only for new designs. The general method of treatment, being based on well-known first principles, cannot, of course, be claimed to be novel.

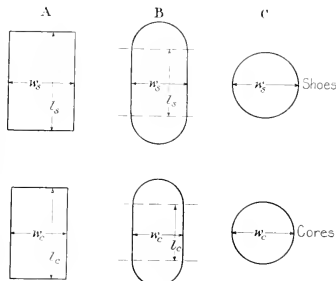

FIG. 2.

of these may again be divided into two sections, the first, hereinafter called "face leakage," comprising the lines that pass between those parts of the shoes and the cores respectively which directly face each other; the second those which emerge from the ends.

- Let L_{st} = face leakage of shoe,
- L_{se} = end leakage of shoe,
- L_{ct} = face leakage of core,
- L_{ce} = end leakage of core.

In addition to the above sub-division we shall have to consider various forms of pole-cores and shoes as used in practice. These are illustrated in Fig. 2, and will be referred to as follows:—

- A Rectangular type.
- B Rectangular type with semi-circular ends.
- C Circular type.

We have to calculate the leakage for types A and B; that of type C is then obtained from B by omitting the face leakage. It is not unusual, of course, to have circular pole-cores with rectangular shoes, or cores of type B with rectangular shoes, and in this case the equation for the shoe of type A will have to be employed in conjunction with formulae for the core of type B or C.

Finally, two different forms of exciting coils will have to be considered, namely, the non-stepped or parallel coil and the stepped coil. In the former the number of ampere-turns per unit of length is constant and the coil is of uniform thickness. In the latter, with the object of the better utilization of the available space, the thickness increases, generally towards the shoe, and so does the number of ampere-turns per unit of length. It will be seen that for a given magnetomotive force the shape of the coil, *i.e.* the distribution of its ampere-turns, does not affect the shoe leakage but only the core leakage.

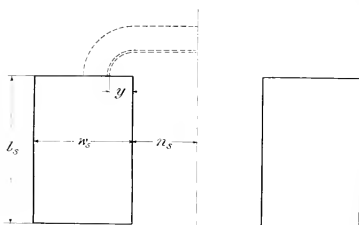

FIG. 3.

Our procedure is therefore as follows:—

Shoe leakage.

- Calculations of L_{s1} and L_{s2} for
 type A;
 type B;
 type C.

Core leakage.

(1) Non-stepped coils.

- Calculation of L_{c1} and L_{c2} for
 type A;
 type B;
 type C.

(2) Stepped coil.

- Calculation of L_{c1} and L_{c2} for
 type A;
 type B;
 type C.

Referring to Fig. 1 the lines $a b$ and $a' b'$ represent planes through the centre of the neutral zone and the shaft. It will be seen that these are equipotential planes of the magnetic system, and hence all lines of force have to pass through them at right angles. The magnetomotive force of the pole drives the flux to these planes, whence it is carried into the adjacent poles under the influence of the magnetomotive force of the latter. We may therefore

consider the section of the magnetic system between the planes $a b$ and $a' b'$ as an independent unit for all future calculations.

SHOE LEAKAGE.

A. Rectangular type.—The leakage flux emerging from the two straight parts of length l_s (Fig. 3) is—

$$L_{s1} = M M F_s (t + g) \frac{2l}{n_s} \dots \dots (1)$$

where the average depth of the path is taken as $(t + g)$ and its average length as n_s (see Fig. 1), whilst $M M F_s$ denotes the magnetomotive force producing the shoe leakage. How to express $M M F_s$ in terms of ampere-turns will be discussed later.

The leakage from the two straight ends is also easily obtained. We assume that the paths followed by all lines are parts of a circle of radius y followed by a straight part of length n_s . This is not strictly correct, since theoretically

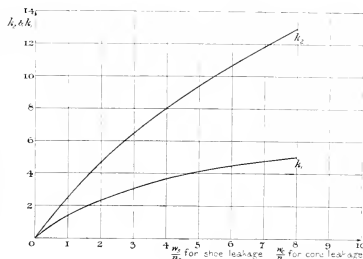

FIG. 4.

the lines must spread out to an infinite distance; but the error thus introduced can only be small. We further make the assumption, not strictly correct, that the depth of the path is $(t + g)$ and obtain

$$L_{s2} = M M F_s (t + g) \int_{v=0}^{v=\frac{\omega_s}{2}} \frac{dy}{n_s + y \pi/2}$$

where ω_s = the width of the shoe (circumferentially).

The integral is easily calculated and leads to—

$$L_{s2} = M M F_s (t + g) 5.85 \log \left(1 + \frac{\pi \omega_s}{4 n_s} \right) \dots (2)$$

It will be observed that for given values of $M M F$ and $(t + g)$, L_{s2} does not depend on the size of the shoe but only on the ratio ω_s/n_s , or, in other words, on the ratio (pole arc)/(pole pitch). We may therefore simplify Equation 2 by writing—

$$L_{s2} = M M F_s (t + g) k_1 \dots \dots (3)$$

where k_1 is a constant for all machines having the same

* See Appendix. I.

ratio of pole arc to pole pitch. The value of k_2 , namely, $5.85 \log \left(1 + \frac{\pi \omega}{4 n_2}\right)$, is plotted in Fig. 4 as a function of ω/n_2 .

Combining Equations 1 and 3—

Leakage of a rectangular shoe==

$$M M F_s (l + g) \left(\frac{2 l}{n_2} + k_2 \right) \quad (4)$$

B. Rectangular type with semicircular ends.—The force leakage remains obviously the same as in the previous case (see Equation 1). The end leakage, however, is considerably altered by the semicircular form. The leakage from a semicircle (Fig. 5) does not at first sight lend itself to a simple treatment. The curved lines of force will again pass at right angles through the equipotential plane a and will emerge at right angles from the surface of the shoe. To meet these conditions and closely to approach the real

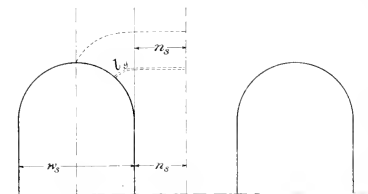

FIG. 5.

distribution let us assume that every line is composed as before of a straight part of length n_2 and of part of an involute, as is shown in Fig. 5. This assumption renders the mathematical treatment comparatively easy and furnishes an exceedingly simple solution of the problem. If l_s be the length of the tube of force shown in Fig. 5 we have—

$$L_s = M M F_s (l + g) \int_0^{\frac{\pi \omega}{4}} \frac{d\psi}{l_s} \quad y=0$$

Now l_s consists of n_2 and the arc of an involute, and we obtain—

$$L_s = M M F_s (l + g) \left[\frac{\pi \omega}{4 n_2} \tan^{-1} \left(\frac{\pi \omega}{4 n_2} \right) \right] \quad (5)$$

It is interesting again to observe that the leakage flux for given values of $M M F_s$ and $(l + g)$ depends only on the ratio ω/n_2 , and hence on the ratio (pole arc)/(pole pitch); and it is thus a constant quantity, irrespective of the size of the pole, provided ω/n_2 remains the same. One might conclude from this that the leakage factor σ of a series of machines of similar design would rapidly decrease as the size of frame increases. This is not the case, however, simply because $(l + g)$ and $M M F_s$ increase as the size of

frame increases; hence the ratio of the leakage flux to the useful flux does not decrease appreciably. The dependence on the ratio ω/n_2 , however, enables us again to simplify Equation 5 for practical use by writing it—

$$\text{Leakage of semicircular ends} = M M F_s (l + g) k_2 \quad (6)$$

where $k_2 = 4 \sqrt{\frac{\omega}{n_2}} \tan^{-1} \left(\frac{\pi \sqrt{\frac{\omega}{n_2}}}{4} \right)$, which is a constant, to be taken from a curve having values of the ratio ω/n_2 as abscissae. Such a curve for k_2 is given in Fig. 4.

Combining Equations (1) and (6) we find—

Leakage of rectangular shoe with semicircular ends=

$$M M F_s (l + g) \left(\frac{2 l}{n_2} + k_2 \right) \quad (7)$$

C. Circular type.—The leakage from a circular shoe is equal to the end leakage of the previous example, stated in Equation 6, which may thus be repeated—

$$\text{Leakage of circular shoe} = M M F_s (l + g) k_2 \quad (8)$$

CORE LEAKAGE.

The chief difference between the core and the shoe with regard to leakage consists in a difference in the magneto-

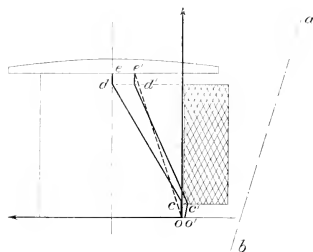

FIG. 6.

motive force producing it. Whilst the magnetic potential of the shoe, $M M F_s$, is the same for all points on its surface, that of the core, commencing at the root and ascending to the shoe, rises from zero, or to be more accurate from a small negative value, to $M M F_s$, and the rate at which it increases depends on the shape of the exciting coils and the magnetomotive force absorbed in the pole itself.

1. NON-STEPPED COILS.

Fig. 6 depicts a pole with a coil of uniform thickness (non-stepped coil), ab represents the equipotential plane midway between two poles, which we take as our zero of magnetic potential. We may then plot the magnetic potential or magnetomotive force producing the leakage flux along the core. This would be represented by the line $o c d e$ if there were no drop of potential in the pole and yoke. Taking this drop into consideration, however, the magnetomotive force is represented by the line $o' c' d' e'$, which at the root of the pole gives a small negative value $o o'$.

* See Appendix, II.

equivalent to the magnetomotive force absorbed in the yoke, and rises to its maximum at d' , this maximum being $M M F_y$, where—

$$M M F_y = \frac{4\pi}{10} \left(\begin{array}{l} \text{total ampere turns} \\ - \text{ampere turns of pole and yoke} \end{array} \right) \quad (8)$$

Without committing a serious mistake we may replace the broken line $a'd'e'$ by the straight line $o'e'$ as long as we are dealing with non-stepped coils, and thus find with reference to Fig. 7—

$$M M F_x = M M F_y \frac{x}{h} \quad (9)$$

A. Rectangular type.—Again referring to Fig. 7 and the

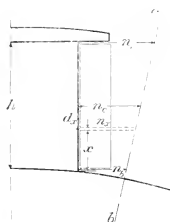

Fig. 7.

notation there indicated we can now calculate the leakage flux L_{ex} passing between the straight faces of length l —

$$L_{ex} = \int_{x=0}^{x=h} M M F_y \frac{2L}{n_s} dx, \text{ where } n_s = n_b + (n_t - n_b) x/h,$$

$$\text{hence } L_x = M M F_y \frac{2L}{h} \int_{x=0}^{x=h} \frac{x dx}{n_b + (n_t - n_b) x/h}$$

which gives—

Core leakage of straight faces (non-stepped coils) =

$$L_{ex} = \frac{M M F_y}{2} \frac{2L}{h} \frac{1}{n_t} \left[\frac{1}{\delta - 1} \left(1 - \frac{\log_e \delta}{\delta - 1} \right) \right] \quad (10)$$

where $\delta = \frac{n_t}{n_b}$, and $n_c = \frac{n_t + n_b}{2}$.

We may simplify Equation 10 by writing it—

$$L_{ex} = \frac{M M F_y}{2} \frac{2L}{h} f_t \quad (11)$$

where $f_t = \frac{\delta + 1}{\delta - 1} \left(1 - \frac{\log_e \delta}{\delta - 1} \right)$ and depends only on $\delta = n_t/n_b$; it may therefore be plotted once and for all as a function of n_t/n_b . This is done in Fig. 8.

The similarity between Equation 11 and Equation 1 is now apparent. The only important difference in its con-

stitution consists in the additional factor f_t , which takes into consideration the effect on the leakage of the angle between the poles, and becomes equal to unity when the poles are parallel, i.e. for $n_t = n_b$.

It requires no elaborate calculation to realize that the leakage from the two ends of the pole may be expressed by an equation corresponding to Equation 3, but again containing the same correction factor f_t .

Core leakage of rectangular ends (non-stepped coil) =

$$L_{e2} = \frac{M M F_y}{2} h k_1 f_t \quad (12)$$

where $k_1 = 5.85 \log \left(1 + \frac{\pi \omega}{4 n_t} \right)$, and may be taken from Fig. 4, so that the total core leakage becomes—

$$L_c = L_{ex} + L_{e2} = \frac{M M F_y}{2} h \left(\frac{2L}{n_t} + k_1 \right) f_t \quad (13)$$

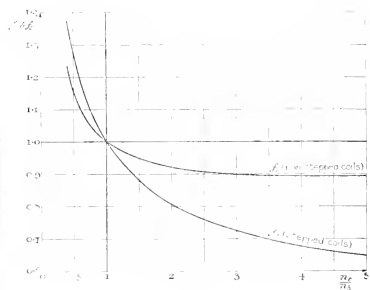

Fig. 8.

In the same manner we find for the—

B. Rectangular type with semicircular ends.

$$\text{Core leakage} = L_c = \frac{M M F_y}{2} h \left(\frac{2L}{n_t} + k_2 \right) f_t \quad (14)$$

where $k_2 = 4 \sqrt{\frac{\omega}{n_t}} \tan^{-1} \left(\frac{\pi}{4} \sqrt{\frac{\omega}{n_t}} \right)$ and is plotted in Fig. 4.

C. Circular type.

Core leakage of circular pole (non-stepped coil) =

$$L_c = \frac{M M F_y}{2} h k_2 f_t \quad (15)$$

2. STEPPED COILS.

The equations for the core leakage so far obtained are all based on the assumption that we are dealing with coils having a uniform number of ampere-turns per unit of length, so that the equation $M M F_y = M M F_x/h$ is sufficiently accurate for our purposes (Figs. 6 and 7). This ceases to be the case, however, as soon as we adopt stepped coils as shown in Fig. 9. Contemplating the extreme case depicted in Fig. 9, where the whole space

* See Appendix, III.

available between the poles is occupied by the field winding, it will be seen that $M M F_w$, i.e. the magnetomotive force acting on the strip of length n_s and depth dx , is proportional to the sectional area of the coil below n_s and may be expressed by

$$M M F_w = M M F_s \frac{(n_c + n_s)x}{(n_c + n_s)h} = M M F_s \frac{n_c + n_s}{2n_c} \cdot \frac{x}{h} \quad (16)$$

It may be noted that the following equations for stepped coils will hold good, although the winding space may not be completely filled up as assumed in Fig. 9, provided only that the distribution of ampere-turns over the coil approximates to that expressed by Equation 16.

A. Rectangular type.

Face leakage =

$$L_{c1} = \int_{x=0}^{x=h} M M F_s \frac{2l_c dx}{n_c} = \frac{M M F_s}{2h} \frac{2l_c}{n_c} \int_{x=0}^{x=h} (n_c + n_s) \frac{x dx}{n_s}$$

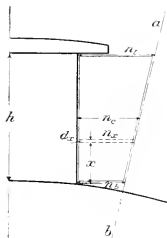

FIG. 9.

The solution of this equation is*—

$$L_{c1} = \frac{M M F_s}{2} h \frac{2l_c}{n_c} \left[2 + \frac{1}{\gamma - 1} - \frac{\log_e \gamma}{(\gamma - 1)^2} \right] \quad (17)$$

where again $\gamma = n_c/n_s$. L_{c1} may be more simply obtained by plotting $\left[2 + \frac{1}{\gamma - 1} - \frac{\log_e \gamma}{(\gamma - 1)^2} \right] = f_2$ once and for all as a function of γ (see Fig. 8). Then the

Core leakage of straight faces (stepped coil) =

$$L_{c1} = \frac{M M F_s}{2} h \frac{2l_c}{n_c} f_2 \quad (18)$$

This formula is identical with the corresponding one for non-stepped coils (Equation 11), the only difference being that f_2 has taken the place of f_1 . This is bound to apply equally to Equations 12, 13, 14, and 15, which will change into—

Core leakage of rectangular ends (stepped coil) =

$$L_{c2} = \frac{M M F_s}{2} h k_1 f_2 \quad (19)$$

* See Appendix, IV.

Core leakage of rectangular pole (stepped coil) =

$$L_c = L_{c1} + L_{c2} = \frac{M M F_s}{2} h \left(\frac{2l_c}{n_c} + k_1 \right) f_2 \quad (20)$$

B. Rectangular type with semicircular ends.

Core leakage of rectangular pole with semicircular ends (stepped coil) =

$$L_c = \frac{M M F_s}{2} h \left(\frac{2l_c}{n_c} + k_2 \right) f_2 \quad (21)$$

C. Circular type.

Core leakage of circular pole (stepped coil) =

$$L_c = \frac{M M F_s}{2} h k_2 f_2 \quad (22)$$

Coil embracing F_c

Coil embracing F_u

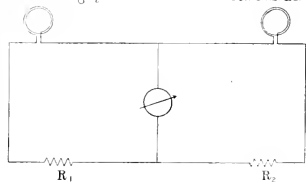

FIG. 10.

Where the stepping of the coils is distinctly less pronounced than that assumed in Equation 16 a factor f will have to be suitably chosen for Equations 20, 21, and 22, intermediate between f_1 and f_2 in Fig. 8.

It may here be noted that the curves in Fig. 8 have been worked out for $n_c/n_s < 1$, i.e. external poles, as well as for

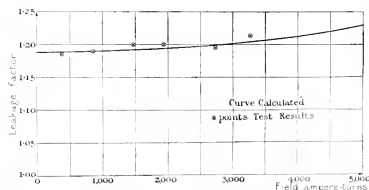

FIG. 11.—Variation of Leakage Factor with Excitation on no load.

$n_c/n_s > 1$, i.e. internal poles. In the former case the leakage is increased by stepping the coils ($l_c > l_s$), whilst in the latter case it is reduced ($l_c < l_s$).

It would, of course, be an easy matter to obtain formulae for the total leakage of the various types by combining and further simplifying the respective equations for the shoe and core leakage, but it appears preferable to the writer to work these out separately, because by so doing the various sources of leakage are better kept under observation, and where the leakage factor is found to be too high

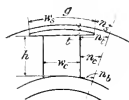

the cause is more readily recognized and the remedy applied.

EXPERIMENTAL VERIFICATION.

In order to test the accuracy of the foregoing formulæ the leakage of a 460-k.v.a. Phenix alternator was calculated for a number of points along its no-load characteristic. The leakage factor σ thus obtained by calculation was then checked on the actual machine by applying a

function of the excitation, the points being the test results, and it will be seen that the agreement is very satisfactory.

In place of a summary a table may here be reproduced (Fig. 12) which has been prepared to expedite routine calculations of the leakage factor in ordinary design work. The formulæ for the shoe leakage of types B and C have been omitted from this table, as such shoes occur so very rarely in practice.

Shoe Leakage

$$L_s = \frac{\text{MMF}_s}{10} (t + g) \left\{ \frac{2}{n_s} + k_s \right\}$$

(For rectangular shoe of length l_s)

Core Leakage

$$L_c = \frac{\text{MMF}_c}{2} h \left\{ \frac{2}{n_c} + k_c \right\} f_c \text{ for non-stepped coils}$$

$$L_c = \frac{\text{MMF}_c}{2} h \left\{ \frac{2}{n_c} + k_c \right\} f_c \text{ for stepped coils}$$

$$L_c = \frac{\text{MMF}_c}{2} h \left\{ \frac{2}{n_c} + k_c \right\} f_c \text{ for non-stepped coils}$$

$$L_c = \frac{\text{MMF}_c}{2} h \left\{ \frac{2}{n_c} + k_c \right\} f_c \text{ for stepped coils}$$

$$L_c = \frac{\text{MMF}_c}{2} h k_c f_c \text{ for non-stepped coils}$$

$$L_c = \frac{\text{MMF}_c}{2} h k_c f_c \text{ for stepped coils}$$

In all Cases

$$\text{MMF}_s = \frac{2\pi}{10} \left\{ \begin{array}{l} \text{Total ampere-turns} \\ \text{Ampere-turns of yoke & pole} \end{array} \right\}$$

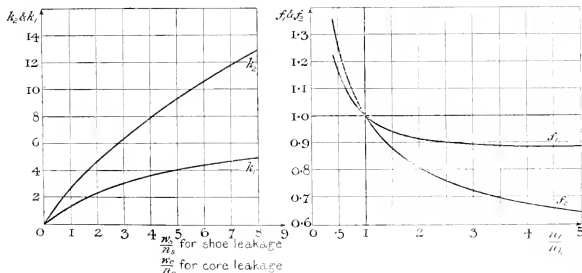

FIG. 12.

simple test, previously described by the author,⁸ the principle of which is briefly as follows:—

Two coils containing an equal number of turns of wire are placed on the machine, one round the root of the pole so as to embrace the total flux F_0 the other against the armature or stator so as to embrace the useful flux F_u only. The coils are connected in series across two resistances of a Post Office box, Wheatstone bridge fashion, with an ordinary millivoltmeter connected to the junctions, as shown in Fig. 10. The resistances are then adjusted so that on breaking or making the field of the machine no deflection is obtained. We then find the leakage factor $\sigma = F_0/F_u = R_1/R_2$.

The leakage factor is immediately given by dividing R_1 by 100, if we keep R_2 constant at 100 ohms and adjust R_1 only until the desired result is obtained. The curve in Fig. 11 represents the calculated values of σ as a

APPENDIX.

1. Derivation of Equation 2 and of the factor k_s plotted in Fig. 4.

$$L_{12} = M M F_1 (t + g) \int_{y=0}^{y=\frac{\omega}{2}} \frac{dy}{n_1 + y \pi/2}$$

$$\int_{y=0}^{y=\frac{\omega}{2}} \frac{dy}{n_1 + y \pi/2} = \frac{2}{\pi} \left[\log \left(n_1 + \frac{y \pi}{2} \right) \right]_{y=0}^{y=\frac{\omega}{2}}$$

$$= \frac{2}{\pi} \left[\log \left(n_1 + \frac{\omega \pi}{4} \right) - \log n_1 \right] = \frac{4}{\pi} \log \left(1 + \frac{\pi \omega}{4 n_1} \right)$$

$$L_{12} = M M F_1 (t + g) 5.85 \log \left(1 + \frac{\pi \omega}{4 n_1} \right) = M M F_1 (t + g) k_s$$

$$k_s = 5.85 \log \left(1 + \frac{\pi \omega}{4 n_1} \right)$$

⁸ Electrician, vol. 50, p. 215, 1907.

II. $I_{\alpha 1}$ (Fig. 10) is, from Equation 5 and of the factor k_2 , plotted in Fig. 4,

$$I_{\alpha 1} = M M F_{\alpha} (t + g) 4 \int_{v=0}^{v=\omega_c \frac{\pi}{4}} \frac{d v}{t_g}$$

where $t = n + \text{arc of involute} = n_s + \frac{\omega_s a^2}{2} = n_s + v^2/\omega_s$,

since $a = \frac{v}{\omega_s/2}$.

Putting $v^2/\omega_s = x^2$, whence $x = v/\sqrt{\omega_s}$ and $d v = \sqrt{\omega_s} d x$ also $n_s = a^2$, whence $a = \sqrt{n_s}$, we find—

$$\int_{v=0}^{v=\omega_c \frac{\pi}{4}} \frac{d v}{n_s + v^2/\omega_s} = \int_{a^2=0}^{a^2=\omega_c \frac{\pi}{4}} \frac{d x}{a^2 + x^2}$$

Now

$$\int \frac{d x}{a^2 + x^2} = \frac{1}{a} \tan^{-1} \frac{x}{a}$$

hence—

$$\int_{v=0}^{v=\omega_c \frac{\pi}{4}} \frac{d v}{n_s + v^2/\omega_s} = \sqrt{\omega_s/n_s} \left[\tan^{-1} \frac{v}{\sqrt{\omega_s n_s}} \right]_{v=0}^{v=\omega_c \frac{\pi}{4}} \\ = \sqrt{\omega_s/n_s} \tan^{-1} \left(\frac{\pi}{4} \sqrt{\omega_s/n_s} \right)$$

$$I_{\alpha 1} = M M F_{\alpha} (t + g) 4 \sqrt{\omega_s/n_s} \tan^{-1} \left(\frac{\pi}{4} \sqrt{\omega_s/n_s} \right) \\ = M M F_{\alpha} (t + g) k_2 \\ k_2 = 4 \sqrt{\omega_s/n_s} \tan^{-1} \left(\frac{\pi}{4} \sqrt{\omega_s/n_s} \right)$$

III. Derivation of Equation 11 and of the factor f_1 plotted in Fig. 8,

$$I_{\alpha 1} = M M F_{\alpha} \frac{2 l}{h} \int_{x=0}^{x=h} \frac{x d x}{n_s + (n_t - n_b) x/h}$$

Substituting $n_b + (n_t - n_b) \frac{x}{h} = l$, and $x = \frac{(l - n_b) h}{n_t - n_b}$,

whence $d x = \frac{h}{n_t - n_b} d l$

$$\int_{x=0}^{x=h} \frac{x d x}{(n_t - n_b)^2} = \int_{l=n_b}^{l=n_t} \frac{h^2}{(n_t - n_b)^2} \cdot \frac{l - n_b}{l} d l = \frac{h^2}{(n_t - n_b)^2} \left[l - n_b \log_e l \right]_{l=n_b}^{l=n_t} \\ = \frac{h^2}{(n_t - n_b)^2} \left[n_t - n_b - n_b \log_e \frac{n_t}{n_b} \right]$$

Now, putting $\frac{n_t}{n_b} = \delta$, $n_t = \delta n_b$, $n_t - n_b = n_b (\delta - 1)$,

$$\int_{x=0}^{x=h} \frac{x d x}{l} = \frac{h^2}{n_b^2 (\delta - 1)^2} [n_b (\delta - 1) - n_b \log_e \delta] \\ = \frac{h^2}{n_b (\delta - 1)} \left(1 - \frac{\log_e \delta}{\delta - 1} \right) = \frac{h^2}{n_b (\delta + 1)} \cdot \frac{\delta + 1}{\delta - 1} \left(1 - \frac{\log_e \delta}{\delta - 1} \right) \\ = \frac{h^2}{2 n_b} \frac{\delta + 1}{\delta - 1} \left(1 - \frac{\log_e \delta}{\delta - 1} \right)$$

since $n_t (\delta + 1) = n_t + n_b = 2 n_s$. Hence—

$$I_{\alpha 1} = M M F_{\alpha} \frac{2 l}{h} \frac{1}{n_s} \left[\frac{\delta + 1}{\delta - 1} \left(1 - \frac{\log_e \delta}{\delta - 1} \right) \right] = M M F_{\alpha} \frac{2 l}{h} \frac{1}{n_s} f_1 \\ f_1 = \frac{\delta + 1}{\delta - 1} \left(1 - \frac{\log_e \delta}{\delta - 1} \right) \quad \delta = \frac{n_t}{n_b}$$

IV. Derivation of Equation 17 and of the factor f_2 plotted in Fig. 8,

$$I_{\alpha 1} = \int_{x=0}^{x=h} M M F_{\alpha} \frac{2 l}{n_s} \frac{d x}{h} = M M F_{\alpha} \frac{2 l}{n_s h} \int_{x=0}^{x=h} \frac{x d x}{(n_s + n_b) x/h}$$

where $n_s = n_b + (n_t - n_b) \frac{x}{h}$

$$\int_{x=0}^{x=h} \frac{x d x}{(n_s + n_b) x/h} = \int_{x=0}^{x=h} \frac{x d x}{x d x + n_b} = \int_{x=0}^{x=h} \frac{x d x}{n_b + (n_t - n_b) x/h}$$

The solution of the former integral is $h^2/2$; that of the latter has been found under III, and is—

$$\frac{h^2}{2 n_b} \frac{\delta + 1}{\delta - 1} \left(1 - \frac{\log_e \delta}{\delta - 1} \right)$$

hence—

$$\int_{x=0}^{x=h} \frac{(n_s + n_b) x d x}{n_s} = \frac{h^2}{2} + \frac{h^2 n_s}{2 n_b} \cdot \frac{\delta + 1}{\delta - 1} \left(1 - \frac{\log_e \delta}{\delta - 1} \right)$$

Now $n_b (\delta + 1) = n_t + n_b = 2 n_s$, therefore—

$$\int_{x=0}^{x=h} \frac{(n_s + n_b) x d x}{n_s} = h^2 \left[\frac{1}{2} + \frac{1}{\delta - 1} \left(1 - \frac{\log_e \delta}{\delta - 1} \right) \right] \\ = h^2 \left[\frac{1}{2} + \frac{1}{\delta - 1} - \frac{\log_e \delta}{(\delta - 1)^2} \right]$$

$$I_{\alpha 1} = M M F_{\alpha} \frac{2 l}{h} \frac{1}{n_s} \left[\frac{1}{2} + \frac{1}{\delta - 1} - \frac{\log_e \delta}{(\delta - 1)^2} \right] \\ = M M F_{\alpha} \frac{2 l}{h} \frac{1}{n_s} f_2$$

$$f_2 = \frac{1}{2} + \frac{1}{\delta - 1} - \frac{\log_e \delta}{(\delta - 1)^2}$$

No. 226.

BRITISH PRACTICE IN THE CONSTRUCTION OF HIGH-TENSION
OVERHEAD TRANSMISSION LINES.

By B. WELBOURN, Member.

(Paper first received 4th November, and in final form 9th December, 1913; read before THE INSTITUTION 8th January, before the BIRMINGHAM LOCAL SECTION 7th January, before the NEWCASTLE LOCAL SECTION 12th January, before the MANCHESTER LOCAL SECTION 13th January, and before the YORKSHIRE LOCAL SECTION 14th January, 1914.)

SYNOPSIS.

Introduction.
Inconsistent state of the law on wayleaves.
Route plans.
Factors of safety.
Mechanical design formulae, etc.
Electrical design formulae, etc.
Description of representative lines employing wood and steel poles.
Wood and steel poles—Corner poles.
Galvanizing and sherardizing of metal-work.
Stays.
Line conductors—Copper and aluminium.
Spacing of conductors—Bracket arms, etc.
Tying-in of conductors.
Insulators—Pins and fixing.
Earthing arrangements.
Protection against atmospheric disturbances.
Telephone and pilot circuits and suspension of lead-sheathed cables.
Telephones.
Guarding of conductors.
Cables and terminal boxes.
Examples of special work.
Sundry details.
Standardization.
Bibliography.
Appendices: (1) Specification for steel masts; (2) Formulae for finding the safe dip of line wires; (3) Ohmic resistance and ratios of reactance to resistance; (4) Drop factor; (5) Table of safe currents for overhead wires; (6) Electrostatic capacity of overhead bare copper conductors; (7) Electrostatic capacity of overhead bare aluminium conductors; (8) Comparison of the physical, mechanical, and electrical properties of aluminium and copper; (9) List of strands recommended for copper and aluminium; (10) Catenary wires; (11) Values of $\sin \theta$; (12) Tests for line insulators.

In our large industrial centres, where electrical energy is usually conveyed to consumers by underground cables,

it is frequently not realized what extensive use of overhead wires is being made in country districts for the same purpose. So far as can be ascertained there are already nearly 1,000 miles of overhead lines in the United Kingdom which are operated at alternating pressures between 2,000 and 20,000 volts inclusive; and of these there are 115 miles in operation or under construction for 20,000-volt working. The author thinks that the time has arrived when it will be of use to engineers and others to have some account of the construction of lines as developed to meet British conditions only, with a view to a helpful discussion of the various problems which are still unsolved. We have no transmission lines over long distances and at high voltages in the sense in which they are understood in other parts of the world. Such lines were designed to meet very different conditions from those obtaining in this country, and they have recently² been fully described before this Institution.

It is not within the scope of this paper to examine the problem of the distance to which it is commercially economical to transmit electricity in preference to carrying fuel, but it may be recorded that our longest direct transmission line is only about 20 miles in length, while one of 40 miles is under consideration.

It may be taken for granted that pole lines have come to stay in rural districts, where low first cost is of paramount importance in enabling supply authorities to give a cheap supply of energy to industrial works, collieries, houses, etc. It is not necessary to state the case for overhead lines at any length, but it may be well to give the following figures for 3-phase transmission to illustrate the saving in first cost between underground cables and overhead lines. In compiling these figures of costs per mile, care has been taken to include everything required for work of the highest

class. Copper has been taken at £60 per ton, and lead at £20 per ton. The copper conductors comprise three of 0.710 sq. in. section in each case. No buildings, transformers, or switchgear are included, and it should be borne in mind that the annual maintenance and depreciation charges on an overhead line are necessarily heavier than on a modern cable system.

Voltage	Cable Laid and Jointed, including Street Work	Overhead Line of equal Kilowatt Capacity
6,600	£ 1,400	£ 900
11,000	1,550	950
20,000	2,100	950

1. The Postmaster-General possesses powers for erecting telegraph and telephone lines, but the procedure to be followed is so cumbersome as to be almost useless. Even these powers are denied to electric supply authorities.

2. Under the Electric Lighting Acts the consent of the local authority must be obtained by a statutory undertaker previous to the erection of overhead wires, whether these are in the public street or on private land.

3. Non-statutory undertakers can dispense with the consent of the local authority and both erect wires on private land and cross public roads so long as the wires cause no obstruction above the roadway.

4. Non-statutory undertakers may erect overhead lines without compliance with the Board of Trade regulations, but the Board has power, if it thinks fit, to order such compliance.

The author thinks that a strong case has been made out to justify the Council of this Institution in making repre-

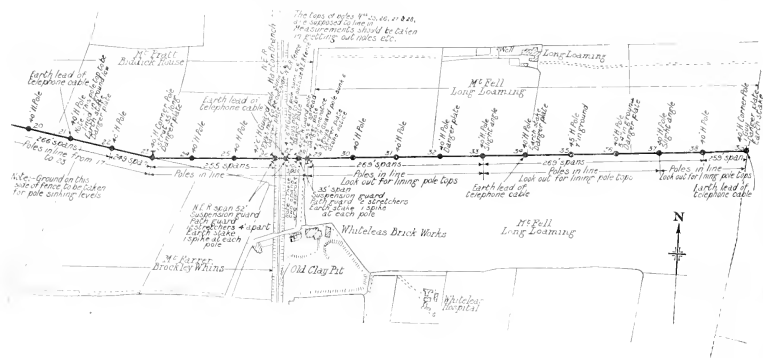

FIG. 1.—Route Map.

Incidentally, this Table shows how little influence the working pressure has on the first cost of an overhead line in this country.

Through this cheapened means of transmission much electrification work is now being undertaken which would otherwise not be commercially possible. The extensive use of overhead lines has thus become of enormous benefit to the manufacturers of electrical plant, cables, and accessories, as well as to the supply authorities and their consumers.

The principal difficulty in pole-line work across country is that arising from the necessity of negotiating wayleaves, and these negotiations are frequently very prolonged. This subject has been fully discussed by Mr. C. Vernier in his Address* (October, 1913) to the Newcastle Local Section of this Institution, and that part of the Address which deals with the inconsistent state of the law on the question of wayleaves, etc., may be summarized as follows:—

* Journal I.E.E., vol. 52, No. 223, p. 17.

sentations to the Board of Trade for the benefit of the electrical industry and all consumers with a view to removing the inconsistencies which exist in the law. At the same time, efforts should be made to secure:—

1. A curtailment of the absolute veto on the construction of overhead wires by a local authority.

2. The local authority's refusal of consent should be made subject to an appeal to the Board of Trade. At present such an appeal is only allowed to power companies' wires in rural districts. The author would further suggest that this one subject should be taken up by itself and that success should not be endangered by making representations on other matters at the same time.

All high-tension lines should be designed to comply with the current regulations of the Board of Trade, or with approved modifications, and it cannot be too strongly emphasized that the success or otherwise of all lines will be very largely dependent on the close attention which is paid both to the design and to the erection of every detail.

For instance, to secure the best results, it is essential that the engineers should survey and set out the line and then prepare and issue to the constructional engineers a route plan giving all essential details of what is required. Fig. 1 gives a copy of such an actual plan which is a model of lucidity. In the author's opinion it is not conducive to the best results or to economical erection for the setting out of the work to be left to the construction engineer to do at the last moment. Another essential is that the clerk of works should be competent and not be hampered by inelastic instructions. In making the survey of the line a useful instrument is Captain Abney's clinometer level fitted with a compass.

FACTORS OF SAFETY.

Considerable criticism was directed some time ago against the requirements of the Board of Trade that the conductors should have a factor of safety of 5 at 23° Fahr., and wooden poles a factor of safety of 10, in both cases taking the wind pressure at 30 lb. per square foot of the exposed effective areas, whereas another Government Department—the General Post Office—only used factors of 4 and 8 respectively and took the maximum wind pressure at 17 lb. per square foot. In both cases accumulations of ice or snow are not taken into account. The Board of Trade has recently made an alteration in its requirements by reducing the wind pressure figure to 25 lb. per square foot, and Revised Regulations were issued covering this and other modifications in May, 1913.

The two cases which are compared are far from being analogons. In the case of the General Post Office the voltage on the wires and the power behind it are not such as are likely to cause any injury to person or animal through shock from a fallen wire; but it is very doubtful whether the G.P.O. figures are sufficiently conservative when one considers the extensive wrecking of telegraph and telephone lines which occurs in every snow-storm that is accompanied by a gale. High-tension power lines are on a different footing. It is the duty of the Board of Trade to prescribe reasonable precautions for safeguarding the public, etc., from fallen wires, and for the maintenance of a continuous supply of energy to those who are dependent on it. Having this duty laid on it by Act of Parliament it is not to be expected that the Board will err on the side of under-cautionsness, and, in view of a few failures of high-tension lines which occurred in the severe storm of January, 1913, in the case of lines that had been most carefully designed and erected to comply with the Board's Regulations, one can scarcely expect that the Board will make any further relaxation in its requirements for some time to come.

It does not seem to be generally understood that the Board is prepared to relax the Regulations in those cases in which it can be shown that wind pressures of 25 lb. per square foot have never been recorded. The Meteorological Department has extensive records of the wind pressures in all important districts of these islands, and they should be consulted prior to designing any line.

MECHANICAL DESIGN FORMULÆ, ETC.

1. (A) For wood poles. (B) For steel poles.

(A) Full particulars of the dimensions of wood poles and 1-ft. breaking stresses are given in the British Post Office Technical Instructions, XIII, dated 1911. Valuable infor-

mation on the strength, etc., of poles is also given in Mr. Christopher Wade's paper⁵ before this Institution.

1. An A-pole is about 4½ times as strong as a single pole comprising one of the legs, when provided with a crossoted brace-block 8 in. × 4 in. and 6 or 8 ft. long about 2 ft. from the butt end, and with an oak key near the top secured by a scarf-bolt and with a tie-bolt about half-way up the pole above the ground line, the spread of the pole being about one-eighth of the length. A second scarf-bolt is employed at the top of the pole.

2. An H-pole fitted with two cross-arms, one tie-rod, and one brace-block, but no trussing tackle, is about 3½ times as strong as a single pole comprising one of its legs.

3. To determine the size of pole required.

Let d = diameter in inches of each line wire,

n = number of line wires,

p = wind pressure in lb. per square foot on a plane surface,

l = length of span in feet,

D = distance of centre of wires to ground-level in feet,

d' = average diameter of pole in inches,

D' = distance of pole out of ground in feet.

Take the effective area exposed to wind pressure as 0.6 of the actual diameter of line wires and poles multiplied by the respective lengths.

Then—

(a) Total wind pressure on the wires acting on the pole at the centre of the wires

$$= \frac{0.6 d \times n \times p \times l}{12 \times 112} = \frac{d \times n \times p \times l}{2240} \text{ cwt.}$$

(b) The resulting stress on the pole acting at 1 ft. from the ground-line is then—

$$\frac{d \times n \times p \times l \times D}{2240} \text{ cwt.}$$

(c) The wind pressure on the pole itself acting at 1 ft. from the ground-line

$$= \frac{0.6 d' \times D' \times p \times D'}{12 \times 2 \times 112} \text{ cwt.}$$

$$= \frac{d' \times D' \times p \times D'}{4480} \text{ cwt.}$$

(The wind pressure on A- and H-poles should be taken as 1½ and 1½ times respectively that on a single pole.)

Therefore, the total 1-ft. breaking stress acting on the pole is the sum of (b) and (c), and this should be multiplied by the factor of safety (10). The size of pole required can at once be determined by reference to P.O. Technical Instructions, XIII.

(B) For steel poles, Messrs. Bullers, Ltd., have kindly furnished the specification which is given in Appendix I.

II. Stress on poles due to change in direction of wires.

Let θ = the angle between the wires,

R = resultant stress in lb. acting along a line which bisects the angle θ ,

p = stress of each span, i.e. the total breaking stress of all the wires in lb. divided by the factor of safety allowed for the wires.

⁵ Journal I.E.E., vol. 39, p. 304, 1907.

Then—

$$R = 2 \times p \times \cos \frac{\theta}{2} \text{ lb.}$$

This stress may be taken up by a stay calculated as in III.

III. Stress in stays.

Let S = stress in stay wire in lb.,

R = resultant stress of line wires in lb.,

θ = angle formed by stay wire and pole.

Then—

$$S = \frac{R}{\sin \theta} \text{ lb.}$$

IV. Stress in terminal pole.

This is equal to the total breaking stress of all the wires attached to it on the line side divided by the factor of safety to which they are stressed.

V. Breaking stress of round insulator pins.

Let W = elastic limit for wrought iron or mild steel,

L = length in inches above cross-arm,

D = diameter of pin in inches,

C = coefficient of rupture: 65 to 80 for wrought iron, and 80 to 100 for mild steel.

Then—

$$W = \frac{C \times 4.7 \times (D^3)}{L}$$

A factor of safety of 4 should be allowed for iron or steel pins in order to obtain sufficient stiffness.

V1. *Breaking stress, etc., of 7/8 and 19/8 S.I.T.G. galvanized steel stay wire.*

No. of wires...	7	19
Weight per 100 yards in lb.	151	415
Breaking stress in lb. :—					
25-ton quality	7,840	21,280
40-ton	12,180	33,060

VII. Average breaking stress for stay rods.

$\frac{3}{4}$ in	10,650 lb.
$\frac{7}{8}$ in	15,900 "
$1\frac{1}{8}$ in	21,900 "
1 in	20,100 "

VIII. Stay baulks.

When buried so as to pull against undisturbed ground, stay baulks may be proportioned as follows :—

Evenly Distributed Load in Tons	Size of Baulk
12	3 ft. 6 in. \times 10 in. \times 5 in.
8	3 " 0 " \times 9 " \times 4 $\frac{1}{2}$ "
5	2 " 0 " \times 10 " \times 5 "

IX. Strength of steel channel cross-arms.

As stated elsewhere, galvanized channel $3\frac{1}{2}$ in. \times 2 in. \times $\frac{1}{4}$ in. (B.S.C. No. 2) is commonly employed. There are very few data available for steel channels, but experiments show that the following formulæ may be safely used to give a factor of safety of 4 and $\frac{3}{8}$ -in. deflection on a single arm of this size of channel.

Let W = maximum weight in lb.,

and L = length in feet of channel arm.

(a) Channel with weight at one end (Fig. 2a)—

$$W = \frac{2750}{L}$$

(b) Channel with weight in centre (Fig. 2b)—

$$W = \frac{5400}{L}$$

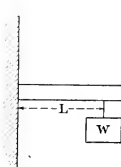

Fig. 2a.

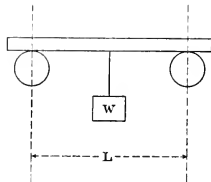

Fig. 2b.

X. Particulars of catenary wires will be found in Appendix X.

ELECTRICAL DESIGN FORMULÆ, ETC.

The following formulæ and particulars are in regular use in designing overhead lines and give very accurate results.

1. To find current in lines.

Let W = watts to be delivered at far end of line,

V = voltage between outer wires at delivery end,

$\cos \phi$ = power factor of the load,

I = current in amperes.

Then—

$$I = \frac{W}{V \cos \phi} \text{ for single-phase lines,}$$

$$I = \frac{W}{\sqrt{3} V \cos \phi} \text{ for 3-phase lines.}$$

2. Voltage loss.

For short lines such as are used in the United Kingdom, capacity may be ignored and the formula $V_e - V$ will give the voltage loss.

$$V_e = \sqrt{(V \cos \phi + V_g)^2 + (V \sin \phi + E)^2}$$

where V_e = voltage at generator,

V = voltage at point of use,

V_g = ohmic pressure-drop in volts,

E = E.M.F. of self-induction,

ϕ = angle of lag corresponding to power factor of load.

There is another and simpler method of ascertaining the loss when the following particulars are known:—

E.M.F. at point of use; kilowatts to be delivered; power factor of load; size of wire; distance between wires; periodicity; length of route.

In a continuous-current circuit the drop in voltage depends upon the current and the ohmic resistance. In an alternating-current circuit the total drop depends not only upon the current and the ohmic resistance, but also upon the self-induction of the circuit and the power factor of the load. In the short overhead lines used in this country the effects of electrostatic capacity may usually be ignored, and no account is here taken of it.

The pressure-drop due to resistance which would result were a continuous current to flow through the circuit, is first determined; then a "drop factor" is found by which the pressure-drop with continuous current must be multiplied in order to obtain the pressure-drop produced by alternating current. The "drop factor" depends upon three things:—(1) the ratio between the ohmic value of self-induction (reactance) and the ohmic resistance; (2) the power factor of the load; and (3) the percentage value of the resistance pressure-drop.

(1) This depends upon the size of wire, the distance between wires, and the frequency. Appendix III gives the ratio of reactance to resistance for conditions which are most likely to occur in practice.

(2) The effect of the power factor of the load is given in Appendix IV, in which the "drop factors" for various ratios of reactance to resistance and various power factors are given. These have been determined by assuming a resistance loss in volts equal to 10 per cent of the pressure delivered.

(3) The percentage value of the resistance pressure-drop has a relatively small effect on the value of the "drop factor," so that the values given, which are determined for a resistance loss of 10 per cent, may be accepted as practically correct for all resistance values not exceeding 15 or 20 per cent. The greatest discrepancy occurs when the ratio is high and the power factor is unity.

3. Self-induction.

The coefficient of self-induction in millihenries per mile of single conductor is $0.0805 + 0.741 \log d/R$,

where d = distance between centres of conductors in inches, and R = radius of conductor in inches.

The ohmic value of self-induction is—

$$2\pi \times \text{periods per second} \times \text{henries.}$$

The E.M.F. of self-induction is—

$$2\pi \times \text{periods per second} \times \text{henries} \times \text{amperes flowing in the conductor.}$$

4. Graphical method of ascertaining the losses in a 3-phase overhead line.

In Fig. 3 B H J is drawn to scale as an equilateral triangle with each side equal to the pressure between the wires at the loaded end (B, H, and J, being the three phases). Then AB, or AH, or AJ, are each equal to the pressure $\div \sqrt{3}$. Draw AC (to scale) equal to the full-load current at the loaded end, lagging behind AB by an angle ϕ corresponding to the power factor ($\cos \phi$) of the load. Draw AD at right angles to AB and of such a length as to represent the capacity current to the same scale as AC. This

assumes that the capacity is massed at the loaded end. Compound AC and AD; this gives the resultant current AE in the line.

Now draw BF (to the same scale as AB) to equal the pressure drop in one wire and parallel with AE. (This pressure drop is equal to AE \times resistance of one wire.) Next draw FG (to the same scale as AB) at right angles to BF and equal to the E.M.F. of self-induction in one wire. Join AG. Then from AG complete the triangle G L K, and the sides GL, or LK, or KG, each give the necessary pressure between the wires at the generating end (i.e. $\sqrt{3} \times AG$).

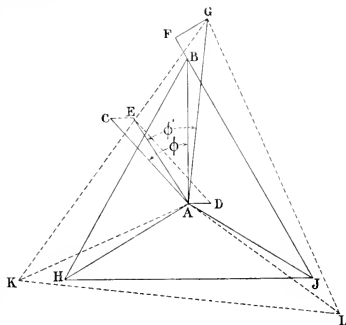

FIG. 3.

The cosine of the angle ϕ is the power factor at the generating end, and therefore the kilowatts delivered to the line will be—

$$\text{Pressure } GL \times \sqrt{3} \times \text{amperes } AE \times \cos \phi \div 1,000.$$

5. Electrostatic capacity.

Overhead bare conductors.

Let C = capacity per mile in microfarads,

d = distance in inches between centres of wires,

r = radius of conductor in inches.

Then for a two-wire circuit—

$$C = \frac{0.0104}{\log d/r}.$$

In the case of a 3-phase circuit with the conductors arranged at the corners of an equilateral triangle there are practically three equal capacities, as is shown in Fig. 4, and in this case the capacity

$$C_1 = \frac{0.0388}{\log d/r}.$$

The capacity current in amperes per mile of cable (assuming that the wave-form of the E.M.F. is a sine curve) will be—

$$1. \text{ For a single-phase circuit } \frac{2\pi \times f \times C \times V}{10^6},$$

$$2. \text{ For a 3-phase circuit } \frac{2\pi \times f \times C_1 \times V/\sqrt{3}}{10^6},$$

where f = periods per second,

and V = voltage between two outer conductors.

Values for copper and aluminium conductors will be found in Appendices VI and VII.

In the case of conductors arranged in one plane the capacity is obtained from the expression $\frac{2}{3}abc$, where a, b, c are the capacities shown in Fig. 5.

6. The Table of safe currents for overhead wires given in Appendix V is based on Professor George Forbes' formula, $I^2 = D^2 \left(\frac{t \pi^2 H}{4 R \times 0.24} \right)$. This is found to be very accurate in practice.

Before discussing details it will be of interest to describe two lines representative of wood and steel pole construction. With one important exception most of the high-tension lines have been built with creosoted wood poles. A representative example of an up-to-date line using wood pole supports is that erected from Scotswood to Burn Pit for the Newcastle-upon-Tyne Electric Supply Company, to the specification of Messrs. Merz & McLellan.

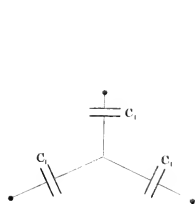

FIG. 4.

FIG. 5.

The main particulars of this line are as follows:—

System of working. 3-phase 40 cycles with earthed neutral.
Voltage between conductors. 20,000.

Voltage between conductors to earth. $20,000 \div \sqrt{3}$.

Conductors. Two horizontal circuits employing wires of 0.10 sq. in. section, arranged on the Merz-Hunter split conductor system.

Conductor spacing. 5 ft. horizontally. 5 ft. vertically.

Conductor sag at 60° Fahr. 5 ft. 6 in.

Average length of span. 85 yards.

Straight line poles. H-poles 32 ft. long and 10½ in. diam. at 5 ft. from the butt. 3 ft. 6 in. centre to centre of poles.

Channel arms on straight line poles. 10 ft. 6 in. long. 3½ in. × 2 in. × ½ in. galvanized.

Terminal poles. H-poles 40 ft. long and 11 in. diam. at 5 ft. from the butt. 12 ft. centre to centre of poles.

Channels on terminal poles. 12 ft. 6 in. long. 5 in. × 2½ in. × ¾ in. galvanized.

Corner poles. H-poles 40 ft. long and 10½ in. at 5 ft. from the butt. 3 ft. 6 in. centre to centre of poles.

Channels on corner poles. 12 ft. 6 in. long.

Insulators on straight line poles. Petticoat pin-type well-cushioned from the metal pin by oiled twine packing.

Insulators on corner poles. Petticoat pin-type well-cushioned from the metal pin by oiled twine packing, but with a second insulator.

Insulators on terminal poles. Suspension type. Three in series.

Earthing arrangements. A continuous 7/12 S.W.G. galvanized steel strand is run from end to end and is connected to an earth plate at every fifth pole. All metal-work on the poles is connected to this wire.

Telephone system. Four-pair telephone cable arranged for superimposed working is suspended from the continuous earth wire. Low-tension telephones are used.

Factors of safety. Strictly in accordance with the Board of Trade requirements of 1913.

Guarding. As shown in Fig. 15.

The terminal pole on the above line is illustrated in Fig. 6, and a corner pole in Fig. 7.

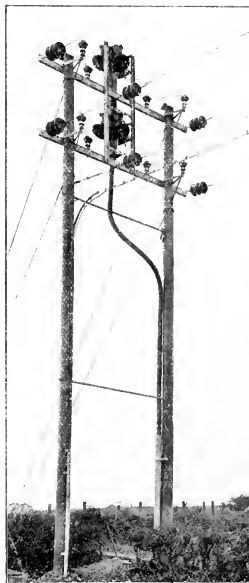

FIG. 6.—Terminal Pole.

The most important lines in the United Kingdom in which steel towers are used are those of the Cornwall Electric Power Company, for whom Mr. J. S. Highfield is the consulting engineer. The North Wales Power Company also have a few miles of lattice steel pole line. The Cornwall Power Company have used both tubular and lattice steel poles on 11,000-volt lines with spans of 240 ft. and 350–360 ft.

The principal features of these lines are as follows :

Steel pole line (No. 1).

Conductors. Two vertical circuits employing solid hard-drawn copper wire, partly 0.125 sq. in. section, continuing with 0.07 sq. in.

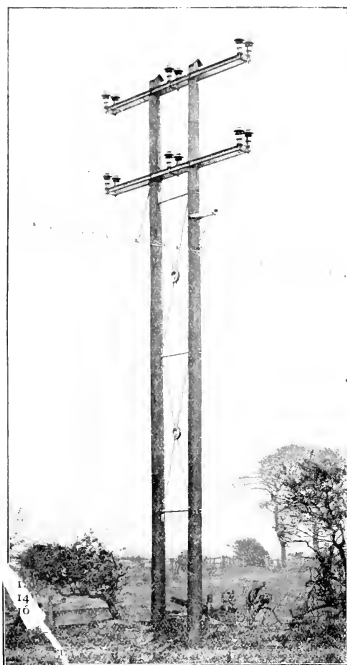

FIG. 7.—Corner Pole.

Conductor spacing. Two top phases 9 ft. 6 in. apart ; two middle phases 10 ft. 6 in. apart ; bottom phases 11 ft. 6 in. apart. Distance between each phase vertically 4 ft.

Conductor sag at 60° Fahr. On the 0.125 sq. in. section 11 ft., and on the 0.07 sq. in. section 10 ft.

Average length of span. 117 yards.

Straight line pole. Total length 50 ft. 8 in. These poles consist of three sections, end base 6 ft. long, and two sections above ground of 19 ft. 4 in. and 25 ft. 4 in., built up of four main angles and braced with similar angles.

Angle poles. Total length 51 ft. 8 in. These poles consist of three sections, one 7 ft. base and two sections above ground 19 ft. 4 in. \times 25 ft. 4 in., built up of four main angles forming a 10 ft. 6 in. square at the ground-level, tapering to a 9-in. square at the top.

Insulators (straight line). Grey suspension type, two in series.

Strain insulators. The same as the straight-line insulators with a different fitting for clamping the wire.

Earthing. A continuous 7/13 S.W.G. phosphor-bronze stranded wire is run from end to end and earthed at five points on the line.

Road crossings. Four poles are placed in the hedge adjoining the road, from which cross wires are supported so that in the event of the power wire breaking it falls on this net. The net is earthed. Barbed wire is wound round the pole at a height of 8 ft. from the ground.

Danger notices. These are placed on every fifth pole and each pole adjacent to the roadways.

Steel pole line (No. 2).

The general construction of this line is similar to that of No. 1. Some of the poles are, however, of a different type, consisting of steel tubes braced together so as to make an A-pole.

Conductors. Two vertical circuits, employing wire of 0.07 sq. in. section.

Conductor spacing. 9 ft. 6 in., 10 ft. 6 in., 11 ft. 6 in. horizontally, and 4 ft. between phases vertically.

Sag at 60° F. 10 ft.

Average length of span. 110 yards.

Insulators. Suspension type, two insulators in series, with phosphor-bronze stranded-wire grammets.

Earthing arrangements. One continuous 7/13 S.W.G. phosphor-bronze stranded wire run from end to end, and connected to earth where a satisfactory earth can be found.

WOOD AND STEEL POLES.

Most of the work already carried out has been done with winter-felled red-fir poles, creosoted by the Bethell process to the G.P.O. standard of an average of 10 lb. of creosote per cubic foot of timber. There is good reason to anticipate a life of 35 to 50 years for these poles if they are left undisturbed and if they are erected within a few months after creosoting. The reason for this is that the free creosote drains into the earth around the pole and forms an additional germicide protection.

In the last two years much interest has been taken in poles creosoted by the Raeping process, but naturally there is no experience yet of their life on the few lines which have been erected in this country. The poles have some advantages over Bethell poles in that they are both lighter in weight and cleaner to handle. From these points of view and in face of the experience obtained in other countries, poles treated by the Powell saccharine process must also be seriously considered in future.

To obtain the best results it is essential that all poles should be selected, dressed, slotted, bored, etc., at the maker's works before the creosoting is done. The maker should be supplied with detailed drawings showing the

finished result required, and the inspection of the poles should take place at his yard whenever possible. When the poles are built up at the maker's works the key-block of A-poles and the brace-blocks of A- and H-poles must be properly marked so as to ensure that they are put together correctly again on the site. Any recess cut in a pole after creosoting should be painted with hot tar. Some engineers have the bottom 9 ft. of the pole covered before erection with a preservative mixture consisting of 14 parts each of Stockholm tar and slaked lime and 7 parts of well-boiled gas tar.

Steel structures before delivery should be coated with bitumastic solution; and on that part of the structure which carries the insulators and so is normally inaccessible with safety, the members should also be galvanized before applying the solution.

The choice between steel and wood poles is mainly a question of first cost plus maintenance charges. In the industrial districts of this country there are many reasons why pole lines cannot be run in a straight line, with the result that the spans usually do not exceed 85 yards in length. For such spans it is cheaper in first cost to employ wood poles which require no after-maintenance. Under exceptional conditions, such as in Cornwall, longer spans can be used, and steel poles can then undoubtedly be employed with advantage. In the author's opinion steel poles should not be employed in smoke and fume-laden districts without the most careful investigation, because experience with them on tramway and railway systems has shown that their rate of deterioration is rapid and the cost of maintenance in painting, etc., is high.

Corner poles of wood.—On most lines it is best to deal with angles by using H-poles which are, when necessary, braced with trussing tackle, and which are equipped with stays and are erected so as to bisect the angle. On heavy double-circuit lines at severe corners it is sometimes necessary to use well-braced 3-legged structures. All corner poles should be erected with only sufficient rake to allow for settlement of the ground, and the whole of the side strain should be taken up by the use of stay wires and kicking blocks. In loose or marshy ground it is often necessary to plant corner poles as well as the kicking blocks in concrete. At corner poles the line wire should be eased round the curve by using two insulators as shown in Fig. 7, and more especially so when solid wire is employed.

Galvanizing, sherardizing, etc., of metal-work.—All channel arms, pins, stay rods, brackets, bolts, etc., should be thoroughly galvanized to the usual standard specification, and where the threads of bolts, etc., are too small to be brushed out while wet in the galvanizing process they should be separately sherardized. Sherardized articles sometimes appear to be rusty after some months' use in the open, but this is only a surface effect.

Stays.—All stay wires should conform with the Engineering Standards Committee's Specification No. 16 for galvanized wire for mechanical purposes. Convenient standard sizes to use are 7/8 and 19/8 S.W.G. galvanized steel strands, which should not in the author's opinion have a breaking strain exceeding 33 tons per square inch, as otherwise the wires will be too hard to be properly workable when nozzling off. The stay wire should be taken three times round the pole or, alternatively, galvanized iron

plates should be fitted to wooden poles, at the point where the stay is fixed, to prevent cutting into the wood. The stay should be taken round a galvanized thimble at the stay rod end. All stay wires should be connected to the general earthing system of a line; but when lines are run in mountainous country where it is difficult to obtain good "earths," it is advisable to insulate the stay wire near the pole by inserting in it an insulator of the tramway globe strain type.

Sometimes it is necessary to put fore and aft stays on poles, e.g. where a line is liable to be damaged by aeroplanes. Selected poles should have stays in the direction of the line whenever the line makes any considerable variation in level. On unenclosed land, so as not to cause injury to animals, all stay rods should be protected by means of wooden cattle-guards securely fixed and painted white to make them easily discernible. It would be better to treat them by the Barnett or Powell processes before painting. The creosoting of cattle guards is a mistake in such cases because they cannot then be painted. In all other cases the cattle guards should be preserved by creosoting them.

The nozzles of all stays should be protected from corrosion by being coated with a high-grade bitumastic paint, and unless the threads of all stay rods are galvanized they should be painted with a mixture of 45 parts tallow, 45 parts coal tar, and 10 parts of mineral pitch, as soon as practicable after installation, to prevent them rusting and becoming useless. In all smoke and fume-laden districts it would be a great improvement to paint all steel and iron work over the galvanizing.

LINE CONDUCTORS.

Probably 95 per cent of the high-tension lines are equipped with copper conductors, chiefly because that metal was first in the field, and while it is very uniform in its characteristics it also has a high scrap value compared with its original cost. Our knowledge of aluminium has, however, made rapid strides in the last three years, and it has now become a competitor that can no longer be passed over without serious consideration. For instance, cold rolling, coupled with improved manufacturing processes in the United Kingdom, has increased the breaking strength of aluminium by 10 per cent over that obtained only a few years ago. After having erected and watched the performance of about 500,000 yards of aluminium conductors (mostly on low-tension lines), the author is very decidedly of the opinion that this metal ought not to be passed over in favour of copper if the total first cost of a line comes out cheaper with aluminium. In cases where sulphur products abound, e.g. in the neighbourhood of coke ovens, aluminium is preferable to copper because it will not be so readily corroded.

The following are some of the high-tension lines on which aluminium has been successfully employed:—

1. War Office, 3-phase lines from Aldershot to Ewshott, etc.
2. War Office, 3-phase lines from Tidworth to Balford.
3. Weardale Steel, Iron, and Coal Company, Thornley to Wingate.
4. Ebbw Vale Steel, Iron and Coal Company.
5. North Wales Power and Traction Company.
6. Fife Coal Company.

There is no standard practice in the case of copper in regard to the use of solid or stranded conductors. On spans up to 50 yards tramway practice may very safely be followed in using solid wires from 11½ S.W.G. up to 40 S.W.G. For longer spans and larger sections the conductors should certainly be stranded because of the additional strength obtainable, and 7, 19, or 37-strand conductors will be suitable. When specifying the breaking strain of the copper, it is very useful to employ a formula of the form suggested by Mr. A. P. Trotter :—

$$T = 30 - 20 D,$$

where T = breaking strain of each wire in tons per sq. in.,
 D = diameter of wire in inches.

In other respects the copper should comply with the British Engineering Standards Specification No. 7, dated March, 1910. The "limit of proportionality" on the wire may be taken at 75 per cent, and the minimum size of solid copper conductor now allowed by the Board of Trade on a high-tension line is No. 11½ S.W.G.

With aluminium it is essential to use stranded conductors, and there should never be less than seven wires in the strand. The breaking strain of the wires employed in the strand can be obtained from a formula similar to the above, viz.—

$$T = 10.5 - 24 D.$$

In order to obtain suitable wire it is suggested that the specification should call for wire having a "limit of proportionality" of 70 per cent approximately, and conforming after stranding with the tests set out in the following Table :—

SUGGESTED TESTS FOR HARD-DRAWN ALUMINIUM CONDUCTORS.

Standard Wire Gauge	Diameter of Wire, Inches	Breaking-strain, Tons per Sq. In.	Extension on a 5 in. length, Per Cent	Wrapping Test
4	0.232	11.00	3.00	Three times round its own diameter on meter on and three times off.
6	0.192	12.00	3.00	
8	0.160	13.00	3.00	
10	0.128	13.50	3.00	
12	0.104	14.00	2.50	
14	0.080	14.50	2.50	
16	0.064	14.75	2.50	

The object of the "wrap test" is to ensure that no brittle wire is used, and it should be noted that compliance with the Board of Trade Regulations is only obtainable by ignoring wires larger than No. 6 S.W.G.

In Appendix VIII a comparison is given of the principal physical, mechanical, and electrical properties of aluminium and copper revised in accordance with the latest information, and in Appendix IX will be found a stranding table for both copper and aluminium conductors, while the sag to be given in erecting a conductor can be obtained from the formulæ set out in Appendix II, allowing a factor of safety of 5 for copper and aluminium at 22° Fahr., when account is taken of the stress due to its weight and to wind, but excluding its elasticity. Wind pressure is to be taken at 25 lb. per square foot, and the effective area of the conductor should be taken as 0.6 of the

diameter multiplied by the length, and no allowance need then be made for the possible accumulation of ice and snow.

Joining conductors.—It is usual to make all joints at insulators and not under strain. There are many ways in which copper conductors can be jointed. The best way known to the author for jointing copper on lines which have to carry heavy loads is by means of the copper braids described by Mr. C. Vernier before this Institution. During calm weather there is no difficulty in making excellent butt-welded joints with blow-lamps on aluminium conductors up to 0.25 sq. in. section, which is the largest section that is likely to be employed in high-tension work.

SPACING OF CONDUCTORS.

Bracket arms, brackets, and pole roofs.—Frequently on single poles carrying one 3-phase circuit a triangular spacing of the conductors is obtained by placing one insulator on a ridge-iron above the zinc pole roof (with which all poles should be fitted) and two insulators on a horizontal arm below it. While this arrangement economizes space, it is not to be recommended because the pole roof is liable to be damaged and because it is difficult to make the top insulator-support sufficiently rigid in all positions, particularly on curves. A better arrangement is that obtained by using three galvanized wrought-iron brackets. Two of these can be arranged on one side and one on the other side of the pole, or they can be put all on one side of the pole if there is any possibility of a second circuit being required later. (In passing, it should be noted that no pole roofs of lighter gauge than No. 14 S.W.G. zinc or No. 16 galvanized iron should be used. Anything lighter is of no use in high winds.) In all really heavy work, such as a duplicate-circuit line, steel channel and not wood cross-arms are now generally used, and there is a growing practice to abandon the equilateral triangular arrangement of the wires on 3-phase duplicate circuits, and to erect the wires of each circuit either vertically or horizontally. The latter is the better arrangement when duplicate circuits are needed, as trouble has been experienced with the vertical arrangement through snow loading down an upper wire until it fouled a lower wire. When duplicate circuits are needed it is an excellent plan to place one circuit on a single pole and the second on another single pole at least one pole length away from it if wayleaves can be arranged. The great advantages of this plan are :—

One circuit can be shut down for repairs, etc., enabling the wiremen to work in safety and quickly, and it is easier to arrange for supply to be given on a ring-main system. The second line should be taken by a different route when possible.

It is not possible to give any general rule as to the spacing to be adopted for conductors for any particular voltage, as this varies with (1) the size of conductor, (2) the length of span, (3) the windage, (4) the sag, and (5) the horizontal or vertical arrangement of the wires; but it may be taken that the spacing on any length of span should not be less than—

3 ft.	for 20,000 volts
2 " 6 in.	11,000 "
2 "	6,000 "
2 "	3,000 "

In deciding the spacing, it is necessary to know the maximum angle of swing of the conductors.

Let θ = maximum angle of swing.

Then—

$$\tan \theta = \frac{\text{wind pressure per foot of conductor}}{\text{weight per foot of conductor}}$$

The maximum deflection in feet from the vertical is $\sin \theta \times \text{sag}$ in feet. In Appendix XI values of $\sin \theta$ are given for copper and the equivalent aluminium conductors for wind pressures of both 17 and 25 lb. per sq. foot. In order to prevent two conductors in a horizontal plane from swinging together, they should, theoretically, be suspended so that their distance apart is more than twice the maximum deflection, but in practice it is safe to assume that the wires will not swing "dead out of phase," and on 80-yard spans to make the spacing equal to the sag of the conductors at 60° F.

Galvanized channel arm of $3\frac{1}{2}$ in. \times 2 in. \times $\frac{1}{4}$ in. standard section is one which is found most useful. The channel arms, being earthed, have one disadvantage on lines which are operated with an earthed neutral and are controlled by any form of instantaneous overload or automatic protective apparatus. Big birds, chiefly crows, stand on the arms and peck at the live wires with results altogether disastrous to themselves, but involving nothing worse than a shut-down of the line and an interruption of the supply. This trouble is usually experienced from May to August while crows are young and presumably learning wisdom. The difficulty has been overcome on several lines by providing porcelain bushes round the insulator pins from the channel arms upwards into the insulator and by clipping pieces of bitumenized fibre conduit on to the arm so as to insulate the bird. On delta-connected lines birds are frequently killed, but no shut-down of the line is involved.

TYING-IN OF CONDUCTORS.

This is one of the most important features in the construction of any line, as bad work will lead to endless trouble and cost in maintenance.

There are three principal methods of tying-in the conductors to the insulators:—

1. Flexible binders.
2. Semi-rigid binders.
3. Rigid clamps.

1. In the author's opinion the flexible binder demands the services of skilful wiremen and is the best both for

pany's lines and has never been known to fail. Fig. 9 shows the successful aluminium binder used on the War Office lines at Aldershot and developed on suggestions

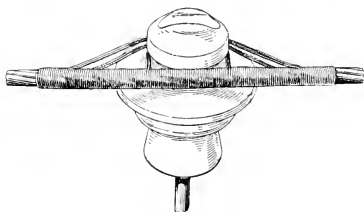

FIG. 9.—Flexible Aluminium Binder.

made by Mr. S. B. Donkin for line conductors up to 0.10 sq. in. For larger conductors the binder shown in Fig. 8 is quite suitable. In both these designs one essential feature is the "pigeon" or chaffer of wire to prevent abrasion of the line wire and of the glaze on the porcelain. Another feature is that flexibility is obtained without the possibility of longitudinal movement of the conductor.

2. The only semi-rigid binder known to the author is that designed and patented* by Mr. G. K. Paton, Chief Engineer of the North Wales Power & Traction Company, and used successfully by him both on 72½ miles of single circuit employing solid copper conductors varying from No. 4 to 20 S.W.G. and on 8 miles of single circuit composed of stranded aluminium. The binders have also been used extensively by the Ebbw Vale Steel Company and the Lambton & Hetton Colliery Company. The Paton binder was designed to overcome troubles on lines which run over mountains and are subject to very severe weather in winter. Under these conditions it was found that the soft-copper flexible binders originally installed stretched and left the line wire loose at the insulator. Vibration in the line wire then caused chafing both of the wire and of the insulator groove, in which the glaze was broken away. Cases were found where the line wire had worn away for 30 per cent of its diameter, while many insulators failed at the groove. The Paton binder is illustrated in Fig. 10. It is made of solid copper wire, No. 4 to No. 6 S.W.G., according to the size of the line wires of copper. With aluminium lines the aluminium binder varies from No. 2 to No. 6 S.W.G. The binder is formed on a special jig to clip round the neck of the insulator, a standard jig being made for each size of insulator. The binder is hooked on the line wire and then bound under tension at the other end with about 15 turns of No. 14 S.W.G. soft binding wire. A leather or pig-skin chaffer is fixed between the line wire and the neck of the insulator, and after 5 years' use it has been found that the chaffer remains as good as new and completely stops the chafing effects on the wire and the insulator. The whole binder remains tight and is yet flexible owing to the cushioning effect of the chaffer. The cost is about the same as that of a well-made

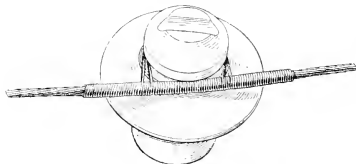

FIG. 8.—Flexible Copper Binder.

copper and aluminium if it is made correctly. Fig. 8 shows the copper binder which has stood the test of several years' work on the Newcastle-upon-Tyne Electric Supply Com-

* Patent No. 5,636, 1912.

flexible copper binder, and about one-fourth the cost of some mechanical clips. It has an advantage over the flexible binder in that no special skill is required for fixing it.

3. There are various forms of rigid clamps in extensive use. When rigid clamps are very carefully fitted by experienced wiremen they appear to give satisfaction, but it is necessary to emphasize the fact that, to get good results, each clamp should be fitted to the insulator on which it is to be used because of the variations in dimen-

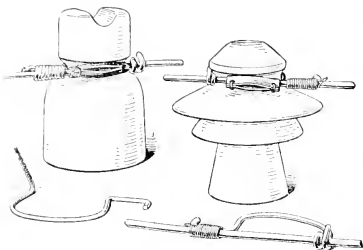

FIG. 10.—Paton Semi-rigid Binder.

sions of all insulators. Some years ago the author investigated two lines on which troubles were experienced, and found that these were due to mechanical clamps. In one case, although well fitted, the line vibration had caused crystallization and breakage of the metal of the clamps. In the other the clamps had been so badly fitted that they were moving, with the result that the glaze of the insulators broke and caused the insulators to fail.

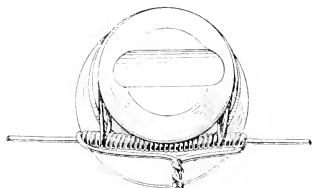

FIG. 11.—Flexible Telephone Binder.

The author is of opinion that rigid clamps are wrong in principle because they reflect back vibrations in the line wire, and it seems certain that ultimately the line wires must crystallize and break at these clamps even if the clamps do not fail first. In this matter much experience has been gained from the breakage of tramway trolley wires at rigid supporting ears.

*Method of making a telephone-line binder (Fig. 11).—*A cushion, of say 24 turns, is first made on the line wire,

and the two ends are then taken around the insulator; in order to avoid having a cross at the back, the wire which starts under the line wire is kept at the bottom of the groove and under the line wire at the other side, and similarly the other wire is kept at the top of the groove and over the line wire. Not less than four turns are now made round the line wire on each side, and the ends are brought together and twisted to prevent the binder spreading.

INSULATORS.

The pin type of insulator is most in favour in this country, and is likely to continue so while pressures remain at 20,000 volts; indeed it is quite reliable up to 66,000 volts. The suspension type of insulator is more suitable for really high pressures such as 100,000 volts, and is then the only practicable way of insulating the conductors. We have seen already that the working voltage has scarcely any influence on the first cost of a line, and the author would like to put forward the suggestion that in view of the rapidly increasing loads in industrial districts all main lines should be designed so that they may ultimately be worked at a higher pressure than that at which they are first operated. For instance, 6,000- and 11,000-volt lines might be designed for a pressure of 20,000 volts, and 20,000-volt lines for 40,000 or 50,000 volts. There can be no doubt that the time is approaching when there must be a further raising of working pressures on main alternating-current high-tension circuits, similar to the big change which was made in passing from 11,000 to 20,000 volts on underground cables eight years ago. The only commercially possible alternative would appear to be the Thury high-tension continuous-current system which has been described before this Institution by Mr. J. S. Highfield on three occasions.*

There is no difficulty in obtaining excellent pin-type insulators, but unfortunately many of those in use have not been of British manufacture. It must be placed to the credit of one British firm of porcelain-makers that it has taken up this question vigorously in the last few years. Late deliveries of insulators by foreign makers are very frequent, and several months sometimes elapse before an order for a few gross of 20,000-volt insulators is completed.

Whether insulators are made in two parts, or not, it is of the utmost importance to insist on the parts being put together in such a way that no air cavity can exist. In two-part insulators this can readily be done by putting in the filling cement very slowly when it is rather liquid. The cement must also be guaranteed to be such that it will not swell or deteriorate on prolonged exposure to damp air.

The colour of the insulators is of importance. Most engineers prefer brown, green, or neutral-tinted insulators as being less conspicuous than white and therefore less likely to attract the attention of stone-throwers, etc. White insulators have the advantage of more readily disclosing where a breakdown has occurred. On lines comprising two or more circuits it is sometimes advantageous to use insulators of different colours for each circuit in order to prevent mistakes and danger to linemen. All insulators should be made of the highest grade porcelain which has been vitrified throughout and is

* *Journal I.E.E.*, vol. 38, p. 471, 1907; vol. 49, p. 848, 1912; and vol. 51, p. 496, 1913.

absolutely non-absorbent of moisture and free from flaws, cracks, or foreign matter. The colouring of insulators is given by the glaze which must cover the entire surface, except the area where joints are made, and must be free from crazing, bubbles, cracks, etc. On completion, insulators should be tested both electrically and mechanically. Messrs. Bulkers, Ltd., have kindly furnished the specification given in Appendix XII of the tests which are recommended for proving the correctness of the design and quality of materials.

Suspension-type insulators can be very usefully employed at terminal poles for insulating the line wires in place of shackle insulators or insulators on pins or swan-necks (see Fig. 6). Such an arrangement materially reduces the cost of a terminal pole on a heavy line. The practice of using shackle insulators on high-tension lines at terminal and corner poles is now almost extinct and is to be condemned because of the weakness of the insulator from the electrical point of view. All telephone-circuit insulators should be of the double-petticoat type when used under power wires.

Insulator pins and fixing.—It is important that all pins should be galvanized and should be stiff enough to withstand every normal strain. They may be fastened to the insulator by a cement which will not swell on prolonged exposure to damp air, or by packing the free space with hemp or twine soaked in linseed oil in such a way as to ensure that the insulator cannot work loose. Both methods have their advocates. The former is to be preferred where skilled labour is not readily obtainable. The latter method requires considerable skill to ensure satisfactory work, but, when properly done, the author prefers it because of the cushioning effect which is obtained.

EARTHING ARRANGEMENTS.

On all the best work a continuous earth-wire, varying in size according to the conditions, is run from end to end of the line either above or below the power wires, and all metal-work on the poles, including a lightning spike, is substantially connected to it. The earth-wire itself should be connected to an earth-plate at every fifth pole by means of a conductor (of ample section for carrying the possible leakage current) which is protected from mechanical damage above ground by a crosstied wood strip or other means, and from corrosion below ground by being buried in pitch or by being painted with a high-class paint such as P. & B.

The connection to the earth-plate must be well made to secure permanent results. One way which the author prefers is to have two bosses cast on the earth-plate with 8-in. centres and to drift into these the terminals of a standard copper tramway bond, to which is bound and soldered the conductor from above. These connections should be liberally painted as before. The earth-plate itself should be 18 in. square and of cast iron not less than $\frac{1}{2}$ in. thick, and should be buried in small coke. Experiments have shown that this is the most efficient size of plate to use. Earth-plates may consist of a number of stakes driven into the ground and cross-connected, or of a 9-ft. cast-iron pipe buried in coke after cleaning off the Angus Smith solution. The author wishes to lay special stress on the necessity of great care being taken with the installation

of the earthing system and its subsequent maintenance, as the safety of human life may be dependent on it. Some high-tension lines are in existence on which each pole has a separate earth-wire coiled up below the base of the pole, and not protected so as to make it impossible for people or animals to come in contact with it above ground. The author believes this arrangement to be really dangerous and would suggest the need for reconstruction.

PROTECTION AGAINST ATMOSPHERIC DISTURBANCES.

When the continuous earth-wire is run above the power wires it is usually placed there with the intention of also affording some relief from atmospheric disturbances, but not from direct lightning strokes. When placed above the power lines, the earth-wire should undoubtedly be of the same metal as the power lines or of bronze, and not of galvanized steel, which has a shorter life than these metals and will, on breaking, foul the power wires and interrupt the supply. This view has previously been put before this Institution by Mr. J. S. Highfield and the author,* who believes that no necessity exists in this country for earth-wire protection above the power lines, as experience of operating high-tension lines shows that lightning troubles are very few and are no more frequent than are mechanical faults on underground cables.

The following are the most important methods which are in use for protection against lightning effects:—

1. Air-core choking coils consisting of not less than 12 turns of line wire are installed in series with each line wire to hold back the high-frequency oscillations until a horn-type air-gap arrester placed on the line side of the coil can spark over. In series with the arrester a non-inductive resistance is employed to limit the flow of current to earth to, say, 10 amperes, and for this purpose a carbon-rod resistance may be employed.

The author does not place any faith in horn arresters erected in the open air, especially in industrial districts, as the air-gap varies in length due to corrosion and deposits of coal and other dust, and, therefore, requires too much attention. Also it has been shown by various investigators that the pressure in the line cannot be relieved by a spark-gap by more than 20 per cent if the series resistance is designed correctly to prevent surging at the frequency of the supply. The author is strongly of opinion that any form of arrester which involves a spark-gap is wrong in principle because of the high-frequency oscillatory disturbances caused by a spark in the circuit.† Serious damage to plant may be caused by these disturbances unless means are also provided to limit the disturbances to the line itself.

2. Electrolytic aluminium arresters combined with a horn arrester have been used on a small scale, but their extensive use is limited by the fact that they need recharging every day from the line, and this cannot be done without considerable expense from locked-up static substations. Full particulars of these arresters have been given by Mr. J. S. Peck.‡

3. Moscicki condensers are coming into favour slowly, possibly because of their high first cost. They have been

* *Journal I.E.E.*, vol. 46, p. 480, 1911, and vol. 51, p. 35, 1913.

† This was written before Mr. Duddell delivered his Presidential Address. The section on "Arcs and Sparks" contains several passages which confirm this opinion. *Journal I.E.E.*, vol. 52, No. 223, p. 1.

‡ *Journal I.E.E.*, vol. 40, p. 498, 1908.

used by the North Wales Power & Traction Company for some years with excellent results, and they are always installed as a matter of course on new lines. They have also been adopted recently by Messrs. Kennedy & Jenkin for the War Office lines from Tidworth to Bulford. The neat arrangement of this arrester on the terminal pole at Tidworth is shown in Fig. 12. The condenser arrester is

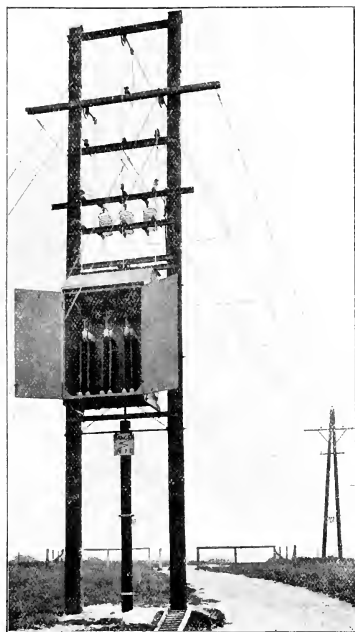

FIG. 12.—Terminal Pole, showing Moscicki Condenser.

attractive from the fact that it is automatic in action and able to discharge rapidly high-frequency disturbances in the line, while it only needs occasional inspection for the replacement of any blown fuses. It may be well to add that these condensers have not sufficient capacity to afford any improvement in the power factor of a line.

4. After much trouble with horn arresters, Messrs. Merz & McLellan have discarded arresters on all lines which are connected to the system through step-up and step-down transformers, and instead they deal with the problem in a novel way. About 10 per cent of the end turns on the line side of the transformers are insulated with special

materials to a thickness of 300 to 400 per cent of the insulation on the remaining turns, and what is required is now well understood by transformer manufacturers. Atmospheric disturbances on the line are reflected back by the end turns of the transformers, and the oscillations are damped out by the ohmic resistance of the line. As the line wires are erected on high-quality insulators it will be seen that only a very high pressure on the line, e.g. a direct lightning stroke, will break down the insulation, and in practice it is found that the outdoor insulators are punctured and the station apparatus is unaffected. The arrangement adopted is effective and cheap and is easily worked in with the general design.

Probably some of the good results on all Messrs. Merz & McLellan's lines are due to their practice of connecting up their lines at both ends through paper-insulated cables, which have a very high resistance to breakdown when momentarily subjected to abnormal pressures. These cables have a low capacity and afford a permanent path to earth for high-frequency oscillations, and thus they are similar in action to the Moscicki condensers.

TELEPHONE AND PILOT CIRCUITS.

Many lines are provided with private telephone circuits and with circuits for the operation of the well-known Merz-Price protective gear. These circuits may be combined in one paper-insulated cable protected by a lead sheath, to which antimony or not less than $2\frac{1}{2}$ per cent of tin is added for the purpose of hardening the sheath. Where two or more telephone circuits are required the cable may be of the multiple-twin type arranged to allow of superimposed working. In any case, for mechanical reasons, the insulation on the telephone conductors should be of the dry, solid type, as its capacity while being higher than that of the air-spaced type is not important on lines up to 40 miles long.

The suspension of the sheathed cable is usually done from the steel-stranded continuous earth-wire when it is run below the power wires. In this case the steel strand should be of 40-ton quality, and the sag given to it and the suspended cable should be such that, on completion, the combination runs parallel to the line wires if possible. The size of suspension strand required may be obtained by reference to Appendix X.

There have been several failures of plain lead-sheathed cables due to the omission of the tin in the sheath and to improper suspension. The difficulties have been very thoroughly investigated, with the result that an entirely satisfactory solution of the difficulty has been found and patented by Mr. C. E. Elder. About 110 miles of lead-sheathed cable on transmission lines have been erected in the Newcastle district under the Elder system during the past two years with such uniformly excellent results that it cannot be made too widely known. Briefly, the system consists of very short chrome-leather hangers which support the cable at every foot and which are prevented from having longitudinal movement by galvanized wire clips sprung on the suspension strand. On level routes every tenth hanger is also clamped to the cable by a galvanized flat spring clip, but on steep hills every hanger should be clamped. Fig. 13 shows the form of the Elder hanger usually employed.

In suspending lead-covered cables on spans exceeding 50 yards measures should be taken to secure that the cable has no severe bends in the vertical plane; and it is thus suspended as shown in Fig. 6. At horizontal bends the cable must be carefully led round the curve by pull-offs on the suspension strand. At terminal poles provision must also be made to carry the cable round an easy bend from the horizontal to the vertical plane in such a

FIG. 13.—The "Elder" Hanger.

way that no movement can take place which would crystallize the lead sheath. The lead sheath should be definitely bonded at every fifth pole to the supporting earth-wire in order to carry away any charges which may be induced in it by the power wires.

On lines which are not protected with automatic gear requiring a pilot cable for its operation and on which one metallic telephone circuit only is required, it is usual to run two No. 14 S.W.G. phosphor-bronze or hard-drawn copper wires, and of these copper is to be preferred. They

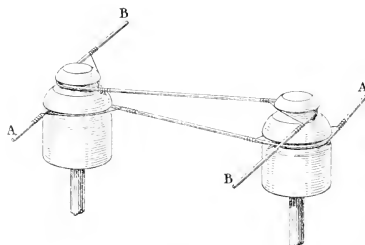

FIG. 14.—Showing a Method of Transposition of Telephone Wires.

may be rotated so as to make one complete revolution at every fifth pole, and in this case it is also advisable to transpose the power wires twice on each route at regular intervals. The rotating arrangement of telephone wires is very unsymmetrical relative to the line wires, but it gives fair results in practice. The author prefers the simpler plan of not transposing the power wires and of not rotating the telephone wires, but of running the latter parallel to one another and transposing them at such regular intervals as may be required. Fig. 14 shows a simple arrangement for effecting the transposition. The author thinks that the cheapness of bare telephone-wire circuits is the only consideration which justifies them. The telephones are most needed at times of breakdown on the

overhead line, and then if a power wire is broken the telephone wires may be either "alive" or burnt through if not already broken by a heavier wire falling on them. Failing these, the telephone circuit may be useless through a broken wire coiling round and short-circuiting it, or vice versa.

TELEPHONES.

When bare telephone wires are used the only instruments which are permissible are those known as high-tension telephones, which are specially insulated in order to make

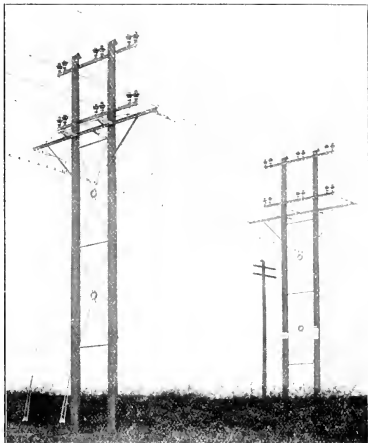

FIG. 15.—Road or Railway Guarding.

it impossible for the telephone user to get a shock due to the considerable voltage which is induced on these wires under normal working conditions, or to contact between the telephone and power wires. A much favoured high-tension telephone apparatus is that made by Messrs. Siemens Brothers & Co., Ltd. It is of the remote-operated pattern, the transmitting and receiving parts being mounted on the back of a marble panel. It is connected to the line through a transformer and the sound is transmitted by insulated hearing tubes so that the user is not brought into contact with any current-carrying part of the apparatus. The protective devices consist of a combination of high-tension fuses and a patent combined vacuum and spark-gap protector. The arrangement described is primarily intended for use at the power house and sub-stations, but there is also a convenient portable equipment for attachment to the telephone wires anywhere on the route or at water-tight protected plugs fixed at definite points. The system is designed to work in proximity to a transmission line with the load balanced between the phases. Should the load be an unbalanced one, it is necessary to fit

drainage coils at stated intervals along the line to remove the inductive disturbances.

When paper-insulated lead-sheathed cables are used for the telephone circuits, the much cheaper low-tension telephones of any good make may be employed, but it is advisable to protect them by heat coils, fuses, and spark-gaps. It is found that, under fault conditions on the line, the fault current partly travels through the lead sheath and sometimes induces current in the cores of the cables of sufficient magnitude to give severe shocks if the apparatus is not thus protected.

GUARDING OF CONDUCTORS.

With the education of the public as to the safety of overhead wires, the methods of guarding lines crossing railways and roads are becoming much simplified, resulting in

line wires it is sometimes advantageous to use a stranded phosphor-bronze suspender to secure lightness. It will be seen that the suspender is anchored to the line wire at the extreme ends and is also attached to it at intermediate points; it seems nearly impossible with this combination for a live wire to fall within reach from the ground. As a further protection, however, an earthed light cradle may be employed as shown in Fig. 15, but it does not seem to be absolutely necessary.

The triangular guard shown in Fig. 16 is a new arrangement which is due to Mr. A. P. Trotter, and has been used on the Ham line of the Twickenham & Teddington Electric Supply Company and by the Fife Power Company. It has the merits of simplicity, low cost, and ease of erection, and is likely to find considerable favour in future work.

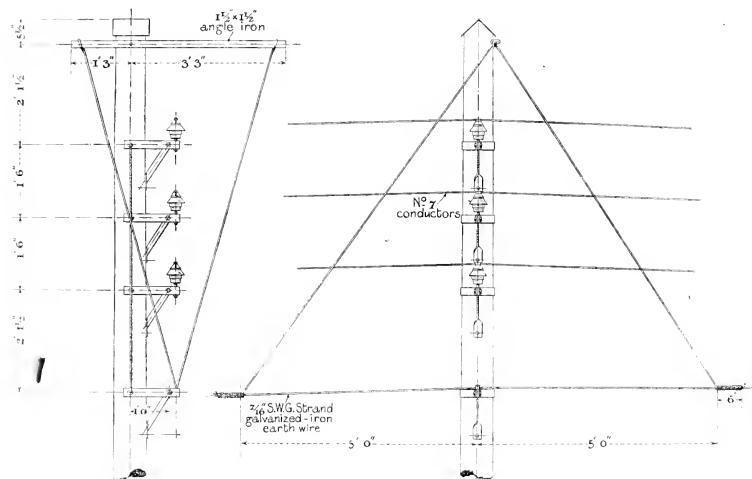

FIG. 16.—Triangular Guard.

reduced cost of construction and enormous gain in appearance. One important 20,000-volt line which crosses a few roads and several miles of mountain moorland much used by tourists, has been equipped throughout with earthed extension pieces of galvanized wrought iron under each insulator. The metal projects for 12 in. on each side of the insulator and the curved portion is nearly semicircular with a radius of 8 in.

The suspension guard shown in Fig. 15 finds considerable favour for road and railway crossings and is used by the Newcastle Electric Supply Company and other undertakers.

The suspender should be of the same sectional area and material as the line wire, but in the case of heavy copper

In cases where important G.P.O. lines are met with, the department requires that bare wires working at a pressure of 3,000 volts and above shall not cross its wires, except by special arrangement, thus involving serious expense in extra terminal poles and underground high-tension cables. In some cases, the department's requirements have been met by using a joint pole for both sets of wires. A good example of this by the Cornwall Power Company is shown in Fig. 17, in which the earthed metal screen between the wires and the caging round the high-tension wires will be noticed. For pressures below 3,000 volts the high-tension conductors may be erected above the department's wires by observing certain requirements, of which particulars

can be obtained from the Engineer-in-Chief. In the case of parallel telegraph and power lines, the department requires a separating distance not less than one and a half times the height of the highest power wire or telegraph wire, whichever is greater.

With the great attention now given to the details of line construction, and with the equipment of lines with automatic protective apparatus, it is becoming exceedingly

circuit by a wire breaking until the wire becomes earthed, which may not occur until the wire has reached the ground. Considering these facts, it would seem that the time is approaching when it will be justifiable to ask for the Board of Trade's consent to run high-tension lines along public roads where the conditions are suitable, and so save the enormous amount of trouble that is involved in obtaining numerous private wayleaves.

CABLES AND TERMINAL BOXES FOR OUTDOOR USE.

Where overhead lines cannot be connected directly to switchgear or transformers by bare conductors, the best practice is to connect up by means of paper-insulated lead-sheathed cables, built when possible to the Engineer-

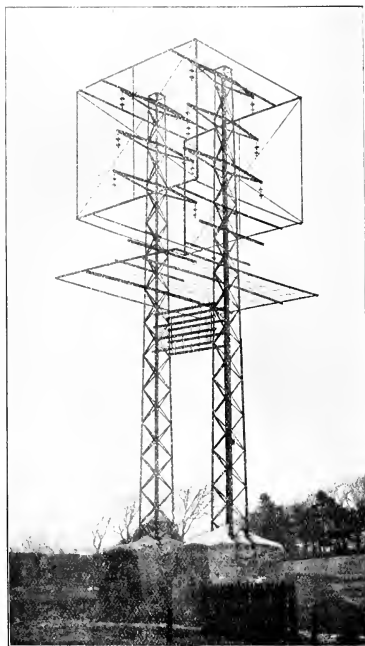

FIG. 17.—Combination Pole for High-tension Wires above and G.P.O. Wires below.

doubtful whether any guarding at all is justifiable on such lines. There is reason to believe that the line wires become "dead" within $1/80$ sec. after the occurrence of a fault or short-circuit or the breakage of a wire when the Merz-Hunter split-conductor system* is employed. The Merz-Price system† will cut out the line within $1/20$ sec. when an earth fault or short-circuit occurs, but it will not deal with the case of the opening of a

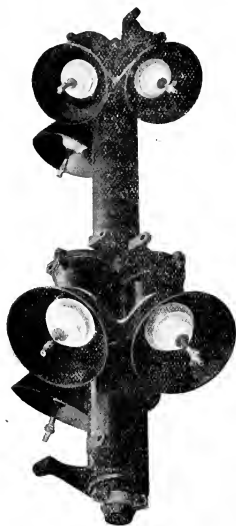

FIG. 18.—Inverted Type of Trifurcating Box arranged for Split-conductor Working.

ing Standards Committee's Specification. These cables are usually armoured with galvanized wire for mechanical protection and to form an additional earthed metallic shield round the cable. The armouring should be protected against corrosion, preferably by compounded tapes. Such cables are also used for bridging across gaps in a line. Experience shows that even at 20,000 volts 3-phase there is no need to make provision for protection against lightning where the cable and the line meet, and, further, that cables can be "teed" off an overhead line with safety.

A cast-iron box fitted with insulators is employed on a

* British Patents, Nos. 4,004 and 26,857 of 1911.

† Ibid., Nos. 3,896-15,796 and 11,364 of 1904.

terminal pole for sealing off the connecting cable at its junction with the line wires. Terminal boxes were very fruitful sources of breakdown until the introduction about three years ago of the inverted box in which the porcelain insulator is considerably protected from wet, snow, dirt, and mechanical damage. The author has never heard of a breakdown occurring at one of these boxes, which are obtainable for all pressures up to 20,000 volts alternat-

filled with high-grade flexible waterproof compound which will not soften appreciably under the direct rays of the sun.

It would be interesting to digress and consider for what pressure cables could be built for use with overhead lines. It can, however, be said with certainty that no pressure is likely to be employed in this country for several years to come which will not find the cable manufacturer equal to the occasion.

EXAMPLES OF SPECIAL WORK.

1. Fig. 19 shows the design of a 4-pole structure which is in use for carrying a 20,000-volt line over a 6,000-volt line. The essential feature in it is the earthed metal platform between the two sets of conductors. Such a platform should be strong enough to permit of two men standing on it simultaneously.

2. Fig. 20 illustrates a neat method of leading-in bare conductors to a station without employing insulated cables. The three horizontal insulators are made in two parts and these are mounted, as shown, on a vertical slate panel which is built into the wall.

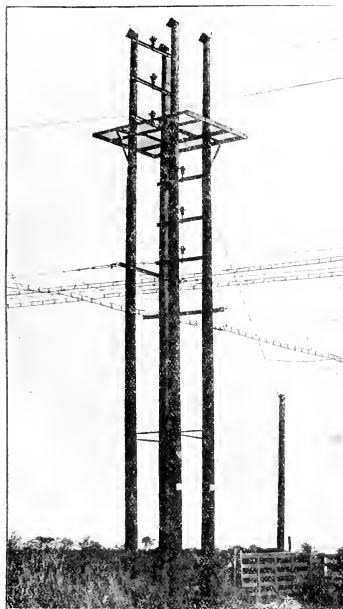

FIG. 19.—Arrangement for 20,000-volt Circuit crossing a 6,000-volt Circuit.

ing current. A patented [®] special form of the box for use with Merz-Hunter split conductor 20,000-volt cable is shown in Fig. 18, and is also to be seen in actual use in Fig. 6 on the terminal pole. Boxes for connecting overhead lines to cables require special design owing to the sudden change in the electrical characteristics of the circuit at the junction. The factor of safety on such a box must be at least $2\frac{1}{2}$, when tested under heavy rain conditions, in order to fulfil all requirements.

The very greatest care should be taken to ensure that all terminal boxes used out of doors should be thoroughly

* Patent No. 29,783 of 1912.

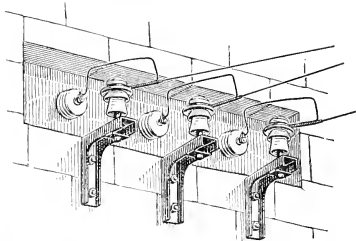

FIG. 20.—Method of Leading-in Bare Conductors to Station.

3. Attention may be called to the fact that the Board of Trade allows a supply to be given from an overhead line through a transformer fixed overhead on a pole, subject to compliance with recently issued regulations. This concession will probably be of much use when negotiations are on foot for obtaining wayleaves.

SUNDRY DETAILS.

(a) To prevent the climbing of poles, each separate pole should be equipped with about 10 turns of 4-barbed wire about 8 feet above ground-level, and the wire should be securely stapled to it. In a few cases *chevaux de frise* have been used.

(b) Each pole should have a zinc number plate (G.P.O. pattern) attached to it by zinc nails at a height of 5 ft. above the ground.

(c) Danger notices should be fixed on at least one pole in five, and on each pole at a road crossing.

(d) During erection some engineers prefer that wiremen should use ladders and not climbing irons for going up the pole. This is a wise precaution, but it must be used with discretion. Usually it is sufficient to use ladders at ter-

mnal and corner poles. In very hilly country the use of ladders may make the cost of erection altogether disproportionate to the benefit derived.

(c) Some engineers stipulate that the tops of poles are to be coated with a mixture of coal tar and creosote before the pole roof is fitted.

(f) Where game guards are required to give warning to flying birds, it is better not to use metal guards, as their swinging has been found to cause cutting of the line wires. It is equally efficient to split and fix on each wire in a span two corks 3 in. long and 1½ in. diameter. The fixing can be done by binding the two halves of the cork with binding wire.

(g) During erection and during repair work line wires should always be "earthed." Where this precaution has been neglected, some cases of bad shock to linesmen have been experienced due to electrostatic charges on the wires.

(h) On completion of erection of a line, it is advisable to subject it to a pressure-test at twice the working pressure for ½ hour, or else to make it alive at working pressure for, say, 2 days before commencing the supply of power.

STANDARDIZATION.

Transmission line designs have passed through several stages, and it would seem that lines employing wooden poles are approaching finality of design in several districts. In their reliability of operation, good mechanical construction, and general appearance, they will challenge a favourable comparison with any other lines in the world. The author suggests that the Council of this Institution might now usefully consider the appointment of a permanent Transmission Lines Committee with a view to evolving standard specifications of materials, watching and reporting on important modifications of the Regulations and practice affecting overhead lines in this and other countries, advising the Council on representations to be made to the Board of Trade, other Government Departments, the Engineering Standards Committee, etc.

In conclusion, the author wishes to express his thanks to Messrs. Merz & McLellan, Messrs. Kennedy & Jenkin, Mr. J. S. Highfield, Mr. G. K. Paton, Mr. Geo. V. Twiss, The Newcastle-upon-Tyne Electric Supply Company, Ltd., and British Insulated & Helsby Cables, Ltd., for information furnished and permission given for its publication, and to his colleagues, Messrs. J. A. Merton and James Nelson, for valuable assistance in the preparation of data and illustrations.

APPENDIX I.

SPECIFICATION FOR MASTS.

General.—The towers are arranged with a joint immediately above the ground-level. This enables the superstructures, *i.e.* all above this joint, to be completely assembled whilst lying on the ground and then swung up into the erect position. The ground joints between the superstructure and the base legs may then be made.

Materials.—The steel used will be Siemens-Martin open-hearth steel, and the sections will be straight, parallel, and free from flaws or other defects.

Rolled steel sections, bars, and plates, would have the following characteristics:—

Ultimate tensile strength	28/32 tons per. sq. in.
Minimum percentage elongation on British standard test piece	20 per cent.

Steel for nuts and bolts or rivets would have—

Ultimate tensile strength	24/28 tons per sq. in.
Minimum percentage elongation on British standard test piece. 26 per cent.

Workmanship.—Main angles will be cold sawn to dead length.

The brace angles and light material in the masts would be sheared to dead length to a jig.

The holes in the main angles and channels where necessary will be drilled to template. The holes in angles and light material would be accurately punched to template.

All parts would be carefully cut and holes accurately made so that when the members were in position the holes would come truly opposite each other before bolting up.

Design.—The masts would be designed in accordance with our standard practice and embody all the latest features.

Factor of safety.—The members would be calculated to have the factor of safety required, upon Claxton Fidler's formula and diagrams.

Wind pressure on structure.—The wind pressure is calculated upon the area of the members, full on the windward side and half on the leeward side.

Inspection.—One per cent of the masts out of the different consignments would be assembled at our works for inspecting engineer's approval as to the accurate fitting of parts.

Testing.—One of each type of mast would be erected at our works and be submitted to mechanical tests as follows:—

1. A horizontal transverse or longitudinal pull* applied at the level of the centre cross-arm.
2. A torsional couple at the centre cross-arm applied by a pull at each end and in opposite directions.
3. A vertical load applied at the end of each cross-arm.

The masts shall withstand the specified tests applied in the above manner without failure.

Packing.—The masts are made to be shipped unassembled and to be erected and assembled on site.

The material of the masts would be prepared for shipment in bundles, and so arranged that each mast would be contained in a separate set of bundles, and no bundle would contain parts other than those of the mast of which it is a component.

The complement of bolts for each mast would be packed in a separate bag, and each different size of bolt making up that complement would be placed in light separate bags within the main bag.

The fastening of the bundles would be arranged to make them as secure as possible against coming asunder in handling for shipment. The bundles would be secured with flat iron tie bars put on hot and $\frac{1}{2}$ in. iron wire would be threaded through the end holes of each bundle wherever possible.

* This pull provides for the loads caused by either wind or wires (in the case of intermediate masts) or pull on the wires (in the case of the main or straining masts) as the case may be, and wind on the structure.

Erection marks.—Each piece or member in the mast would be marked with an erection number corresponding to the numbers on the erection drawings.

Erection drawings.—The necessary quantity of erection drawings would be supplied.

Guarantee.—We guarantee the masts as being scientifically and correctly designed to withstand the calculated loads, and that they would be made of the best material for the purpose and the highest class of workmanship.

Weights.—The weights of the masts given are dependent upon the usual permissible rolling margin of 3 per cent up and down.

Painting.—The material of the masts would be brushed with steel brushes, and specially treated with a continuous covering of bitumastic solution applied before leaving the works.

Nuts and bolts.—The nuts and bolts would be supplied to Whitworth standards and arranged to give good fitting in the holes and so that the unthreaded portion only comes through the holes.

Spares.—The quantity of nuts and bolts would include an allowance of 5 per cent for spares.

Danger plates.—Danger or warning plates for the masts, unless otherwise stated, are not included.

Insulator fixings and earth-wire clamps.—Unless otherwise stated, clamps for fixing lightning wires or clevises for fixing suspension insulators to the masts are not included.

Climbing irons.—In cases where the bracings of the masts are placed close together a man can scale up these, and therefore climbing irons are not included. In cases, however, where the bracings are not sufficiently close together to be readily scaled, then the necessary number of climbing irons are included.

APPENDIX II.

FORMULÆ FOR FINDING SAFE DIP OF LINE WIRES, TAKING INTO ACCOUNT WIND PRESSURE.

$$(1) d = \frac{Pw}{8s} \quad (2) d_t = \sqrt{d^2 + T \left(T \times \frac{3}{8} k \right)}$$

where l = length of span in feet,

d = dip in feet at minimum temperature (22° F. in England),

d_t = dip in feet at maximum temperature (75° F. in England),

s = stress at minimum temperature in lb. = breaking stress of wire in lb. \div factor of safety.

$$w = \sqrt{W^2 + P^2}$$

W = weight of wire in lb. per foot,

P = $0.050 \times$ wind pressure in lb. per sq. ft. \times diameter of wire in inches,

T = difference in degrees F. between minimum and higher temperature,

k = coefficient of expansion per degree F. (0.0000093 for copper and 0.000136 for aluminium).

Where $T = 53^\circ$ F. then $(T \times \frac{3}{8} k) = 0.000174$ for copper, 0.00027 for aluminium, and 0.0001214 for steel.

(No allowance need be made for the possible accumulation of ice or snow.)

NOTES.—(a) The resistance is given per 1,000 yards of 2-wire circuit, i.e. the actual length of wire is 2,000 yards. The resistances given are for hard-drawn copper wire.

(b) In 3-phase 3-wire circuits the conductors are supposed to be spaced at the corners of an equilateral triangle with the distance between corners as given above.

(c) From this Table can be found the ohmic value of self-induction (reactance) per 1,000 yards of a 2-wire circuit—resistance \times ratio.

(d) The self-induction in millihenries per 1,000 yards of a 2-wire circuit = $\frac{\text{resistance} \times \text{ratio} \times 1000}{2\pi \times \text{periodicity}}$.

APPENDIX IV.

VOLTAGE LOSS IN ALTERNATING-CURRENT OVERHEAD CIRCUITS.

Drop-factors when voltage lost in resistance is 10 per cent of the delivered voltage.

2/0	0.0951	172	236				

NOTE.—An aluminium cable will carry 14 per cent more current for the same temperature rise than a copper one of equal resistance, but the voltage drop will necessarily be greater.

APPENDIX VI.

CAPACITY (ELECTROSTATIC) IN OVERHEAD BARE COPPER CONDUCTORS.

The following Table gives the capacity, in microfarads per 1,000 yards of line in a 2-wire circuit, of different sizes of conductors with various spacings between them. In the case of a 3-phase circuit there are practically three equal capacities, as was shown in Fig. 4, and C_1 will equal twice the figure given in the Table.

APPENDIX VIII.

COMPARISON OF THE PHYSICAL, MECHANICAL, AND ELECTRICAL PROPERTIES OF ALUMINIUM AND COPPER.

Property	Aluminium	Copper
Electric conductivity (silver = 100)	58.5	97.5
Coefficient of linear expansion per degree C.	0.000245	0.000167
Coefficient of linear expansion per degree F.	0.000136	0.000093
Specific gravity, cast ingots	2.706	8.78
Specific gravity, rolled or drawn	2.71	8.95
Tensile strength in lb. per sq. in. No. 4-No. 16 S.W.G.	24,600-33,000	55,700-62,500
Tensile strength in kg. per sq. mm.	17-23	38-44
Elastic limit (limit of proportionality) as per cent of tensile strength ...	70	75
Modulus of elasticity, in lb. per sq. in.	9,800,000	16,000,000
Modulus of elasticity, in kg. per sq. mm.	6,905	11,200
Specific resistance, in microhms per cub. cm. at 60° F. (15.5° C.) { soft	2.827	1.696
Specific resistance, in microhms per cub. cm. at 60° F. (15.5° C.) { hard	2.884	1.730
Specific resistance, in microhms per cub. cm. at 0° C. (32° F.) { soft	2.667	1.600
Specific resistance, in microhms per cub. cm. at 0° C. (32° F.) { hard	2.768	1.660
Resistance of conductor 1,000 yards long by 1 sq. in. in cross-section { soft	0.04008	0.02404
Resistance of conductor 1,000 yards long by 1 sq. in. in cross-section { hard	0.04089	0.02453
Coefficient of increase of resistance with temperature { per deg. C.	0.0032-0.0040	0.0038-0.0043
Coefficient of increase of resistance with temperature { per deg. F.	0.0018-0.0022	0.0021-0.0024
Weight per 1,000 yards by 1 sq. in. nominal section, in lb.	3.520	11.700
Weight per 100 feet by 1 sq. in. nominal section, in lb.	117.3	392

APPENDIX IX.

LIST OF THE STRANDS RECOMMENDED FOR HARD-DRAWN COPPER AND ALUMINIUM CONDUCTORS FOR USE ON OVERHEAD LINES.

Actual Effective Area	Copper		Equivalent Aluminium for Equal Resistance	
	Strand	Approx. Weight per Mile	Strand	Approx. Weight per Mile
Sq. in.	S.W.G.	lb.	S.W.G.	lb.
0.025	7/0.068	530	7/0.088	267
0.05	7/0.096	1,056	7/0.124	532
0.075	7/0.118	1,585	7/0.152	798
0.10	7/0.136	2,110	7/0.176	1,070
0.15	7/0.167	3,180	12/0.164	1,600
0.20	7/0.192	4,200	19/0.151	2,145
0.25	7/0.215	5,275	19/0.169	2,665
0.30	19/0.143	6,345	19/0.185	3,210
0.40	19/0.165	8,450	19/0.214	4,310
0.50	19/0.184	10,480	37/0.171	5,350
0.60	37/0.145	12,700	37/0.187	6,400
0.75	37/0.162	15,800	37/0.209	7,990
1.00	37/0.187	21,100	37/0.242	10,700

NOTE.—The areas tabulated are not the nominal areas recommended by the British Engineering Standards Committee. The effective area is that of a solid copper rod having the same resistance as that of the given strand.

APPENDIX X.

CATENARY WIRES.

The following Table gives the size of galvanized steel catenary strand necessary to carry another cable, assuming the following dips at 22° F. and allowing a factor of safety of 5 and a wind pressure of 25 lb. per sq. ft.

Span in feet	105	120	135	150	165	180	195	210	225	240	270	300
Dips in inches at 22° F.	18	23.52	29.76	36.74	44.40	52.90	62.08	72	82.76	94.04	110.02	126.04
Equivalent Dips at 60° F. in inches	21.5	27.12	33.35	40.43	48.1	56.62	65.75	75.7	86.5	97.9	113.7	130.7

Let A = weight per foot of carried cable, S = diameter in inches of carried cable, then $A + 1.5625 S^2$ = the figure given in the Table.

Example: To find the size of the catenary cable necessary to carry a cable of 0.725 in. diameter and weighing 0.5 lb. per foot; span 210 ft., with a dip of 72 in. at 22° F., or 75 $\frac{3}{4}$ in. at 60° F.

We have $A + 1.5625 S^2 = 0.5 + (1.5625 \times 0.725 \times 0.725) = 1.072$. From the Table below it will be seen that either a 7/10 S.W.G. 40-ton quality, or a 7/12 S.W.G. 60-ton quality, would be suitable.

Number of wires in strand and size of each wire. S.W.G.	7/8	7/9	7/10	7/11	7/12	7/13	7/14	7/15	7/16	7/17	7/18
Values of $A + 1.5625 S^2$, 40-ton quality	2.8187	1.907	1.0841	0.6587	0.3814	0.1852	0.091	0.04763	0.02052	0.009224	0.00358
60-ton quality	8.488	5.813	3.435	2.07	1.325	0.732	0.3750	0.21062	0.11052	0.05443	0.02486

APPENDIX XI.

The following Table gives the maximum angle of swing on overhead conductors, assuming a steady wind pressure of either 17 lb. or 25 lb. per sq. ft.

Tan θ = (wind pressure per foot of wire) \div (weight per foot of wire). The maximum deflection in feet from the vertical = $\sin \theta \times$ dip in feet. The distance between two conductors in the same horizontal plane should be, in theory, more than twice this maximum deflection, though this is not always practicable or necessary.

Copper Conductors				Aluminium Conductors of Equal Conductivity				
Nominal Area in square inches	Wind pressure 17 lb. per square foot		Wind Pressure 25 lb. per square foot		Wind Pressure 17 lb. per square foot		Wind Pressure 25 lb. per square foot	
	Sin #	# to the Nearest Degree	Sin #	# to the Nearest Degree	Sin #	# to the Nearest Degree	Sin #	# to the Nearest Degree

APPENDIX X11.

SPECIFICATION.

Testing.—The following tests comprise all that are necessary to prove the correctness of design and quality of material, and are those to which we generally work.

Design test. (To prove suitability of design).—The insulator is subjected to a gradually increasing voltage until it flashes over :—

- (1) With the surface of the insulator dry: this is known as the "flash over voltage dry."
- (2) Under standard precipitation of 1 in. of rain in 5 minutes at an angle of 45° this is known as the "flash over voltage under spray."

NOTE.—Owing to the ordinary variations in the barometric pressure, temperature, and humidity of the atmosphere, flash over voltages necessarily vary 5 per cent up and down.

The insulator is immersed in oil and subjected to a gradually increasing voltage to ascertain its puncture voltage under oil.

A gradually increasing mechanical load may be applied to the insulator to ascertain its ultimate mechanical strength.

Routine tests. (To prove the soundness of each insulator).—Each insulator is subjected to a predetermined voltage known as the "test voltage dry" for 5 minutes, such test being less (usually about 20 per cent) than the "flash over voltage dry."

The standard test pressures are as follows :—

PRESSURE IN KILOVOLTS.

Working Voltage	3,000	6,000	11,000	20,000
Flash over dry ...	46	68	92	105
" under spray ...	27	43	62	74
Puncture ...	74	90	120	130
Test voltage ...	35	55	72	84

A predetermined mechanical load, usually based upon a factor of safety of, say, 4 on the maximum working load of the insulator, is applied to each insulator for 10 seconds; this is known as the "Mechanical Test." These tests are usually only taken on suspension-type insulators.

IRONWORK.

Mechanical tests.—In the case of fittings on suspension insulators these are usually tested when cemented up together with the insulator. As the pin-type insulator will always stand a load that the spindle is capable of carrying, it is usual to test the spindle separately by fixing the spindle to its shank and applying a predetermined load to the end which goes into the insulator and at right angles to the spindle.

DISCUSSION ON

"THE EMPLOYMENT OF POWER IN H.M. POST OFFICE." *

BEFORE THE INSTITUTION, 18TH DECEMBER, 1913.

Major
O'Meara.

Major W. A. J. O'MEARA: I take it that one of the most important functions of an engineer is to eliminate unskilled labour in every sphere of activity. The author has shown how he and those who are associated with him are engaged in solving this very great problem. I have not seen the statistics in relation to the subject, but I have always thought that in no industry could there be a larger percentage of unskilled labour than in the field of transportation. I think we may say that the greater part of this paper deals with problems connected with transportation, although certainly of a very special kind. I do not think the author claims that what he has been telling us is altogether new, or that if he had his own way all the things that he has been describing would have come into existence in their present form at the present time. Take, for instance, street pneumatic tubes in connection with the telegraph services. As a matter of fact, since the development of telephones one would hardly have thought there was any necessity at all for street tubes for the telegraph service.

In many countries users are encouraged to telephone their messages into the office from which they will be transmitted by the telegraph operators. In some street tubes a message takes, I think, about eight minutes—or nearly eight minutes—to travel a little over two miles, and it is really in this direction that time is lost in handling telegrams. In these days of rapid transit, when we can travel such a distance in a motor omnibus in very nearly the same time, it will be seen that there is not a very large field for street pneumatic tubes as a new proposition in relation to the telegraph service. Of course where they exist and there is no other means of surmounting the difficulties, it is right and proper that they should be used and improvements effected such as those described in the paper. There are very few countries where the development of street pneumatic tubes in connection with telegraph services alone has taken place to the same extent as in England. The pneumatic tube question deals only with one part of the problem relating to the acceleration of the

Major
O'Meara.

telegraph service; but I do not wish to take up too much of the time of this meeting, and will now leave the subject of telegraphs for that of posts. The author has also dealt with another aspect of the elimination of unskilled labour. I do not think it can be said that much progress has been made in any country in the direction referred to in the paper in relation to the introduction of machinery in connection with the sorting of letters. As a matter of fact, the problem in question interested me some eight years ago, and I had a model made which I submitted to the Post Office; but I found it practically impossible to interest the authorities. The models were merely inspected and the matter shelved. A few months later I went over to America and there in a Chicago post office I saw—I will not say a really complete installation—but something which went very far towards being a very complete installation of machinery in connection with the handling of letters in bulk and for facilitating the sorting processes. I came back to this country and I discussed the matter with Mr. Gunton, and now he has told us in his paper what he has been doing. Although I have not seen the machinery described by Mr. Gunton, I have, nevertheless, read his description of it, and I may say that he has, in my opinion, made very great improvements on what I saw in America; and in this matter I think he is leading the world.

Mr. C. H. WORDINGHAM: This paper is valuable because it deals with many matters which are official and are not often published; and it gives members a general idea of advances in work with which they are usually by no means familiar. There are just a few points in the paper upon which I should like to comment, mostly in the way of asking for information. I should like to ask the author whether he has found it possible in connection with this multiplicity of services, many of which are repetitions of one another, to go far in the direction of standardization of apparatus. I know by experience how difficult it is to standardize, and I should like to know whether he has been able to do much in that direction: whether he has found it possible to standardize machines for similar services; or whether, if he considers it is not expedient on account of the danger of stagnation in design and the likelihood of throwing the work into the hands of a few makers, he has found it possible to standardize details which, perhaps, are common to a large number of machines. With regard to the arrangement of the power station whereby the low pressure is thrown up to keep the high pressure going in case of breakdown, it would be interesting to know what safeguards are employed to prevent the supply being given from the low-pressure side on a main from which the high pressure is designedly cut off, because it seems to me there might be in certain circumstances a very great element of personal danger if pressure were put on at the sub-station end when the supply was cut off from the generating-station end. On page 111 the use of steam cooking is mentioned as one of the reasons why it was difficult to show economy in replacing the local steam-generating plant with purchased energy. It would be interesting to know whether it has been found commercially practicable to replace steam cooking by electric cooking. Some particularly interesting information is given with regard to the comparative merits and cost of electric lifts and hydraulic lifts, and it would add, I think, to the completeness of the paper if the

author could give us a comparison as regards efficiency, first cost, running cost, and freedom from breakdown between the various kinds of lifts referred to. Then again, I gather that ventilation is in all cases carried out by exhaust fans and not by forcing air into the buildings. I should like to know what kind of fans the author finds most efficient for that purpose, and also what his experience has been of the effect of ozonizers upon the staff in the office in which these are used. I have recently heard it stated that ozone has no germicidal properties, that it simply substitutes one smell for another, and that in large quantities it is poisonous to both man and beast.

Mr. W. SLINGS: I am very glad that the author has been given this opportunity of placing before the Institution some record of the great work which has to be undertaken by the Engineering Department of the Post Office. The field which he has covered, as he says, is incomplete: for example, he omits to mention that we are shipowners, that the Engineering Department has its own small fleet of ships, and that those vessels are employed in the repair and maintenance of the large number of submarine cables which there are around these shores. There is, however, one point which concerned me recently—it is perhaps a little outside the subject of this paper—and that is the object which the Post Office engineers have in introducing new ideas. I want, first of all, to impress upon the members of this Institution, if it be necessary, the fact that we do not, as has been suggested, undertake these investigations, nor attempt to introduce any new idea for the sake of amusement or to fill in spare time—we are not in the position of looking out for something new to keep our minds from rusting. I make that remark especially in reference to the new railway, concerning which there are some who think that we do not need it: there are some who think that if we do need it, perhaps we do not know how to make it; and there are others who, if they believe we know how to make it, think that we shall not know how to use it. But, for all that, the fact remains that we are crowding the streets with our mail-vans, and we are suffering delays owing to the streets being crowded by other users. We want the railway, and we are very certain that the railway will prove remunerative, that is to say, that the railway will result in an actual financial saving. In this connection there is one further point which is perhaps worth mentioning, namely, that we are never in the position of undertaking any of these works without being first able to demonstrate to those who control the financial side the actual and absolute fact that on a financial basis we are working upon right lines, that is to say, that we are going to effect a saving as compared with present methods. If there is anything that is necessary to demonstrate the reality of the pressure which is put upon us when we have to start these new works, it is the fact that at the present moment we have a staff of 22,000 men engaged in maintaining and extending our work, and although we have this large number of men we do not manufacture anything that we can get made for us. That is to say, we first of all make one machine, equip it, run it, and try it, and if it proves useful we draw up a specification and then call in the contractors and ask them to go and do likewise—if they can. But there are many instances where we actually find that a contractor does not, because presumably he cannot, work more economically

than we can work, and then we cannot put the thing out to contract; but I am happy to say that I am now trying a very large extension in this direction with a view possibly to increase the scope of the public and commercial interest in our work. Up to the present moment we, like other users of underground cables, have generally bought the cable, drawn it in, and jointed it ourselves. We are placing very extensive contracts now for the manufacture, laying, and jointing of those cables: it is perhaps problematical whether we shall succeed commercially; but I do hope that this first trial will amply demonstrate the fact that a contractor can lay and joint a cable. The introduction, very largely under Mr. Gunton's direction, of motors, cables, and engines for the working of our underground tubes, has been to a great extent forced upon us. Many of the older staff did not like to see recently the old beam engines removed from the General Post Office. Those engines had done their best for close upon 40 years, and apparently they could have gone on for another 40 years. But they had served their day and generation, and they had to be scrapped, not because they were either worn out or useless, but because they took up too much room, and undoubtedly the advance of electrical engineering has enabled us to remove, as in other fields of engineering, large machinery, and to substitute something much smaller and at the same time more powerful. Although we have so many different applications of electricity now to our mechanical operations, and although we do certainly use small currents for much of our work, I think it must be conceded that as an electrical engineering concern, even when it comes to using things in a very large way, the work of the Post Office is worthy of some consideration. It may surprise some members to hear that in the case of a telephone exchange, which is always associated by the public with minute currents, we use secondary batteries having a capacity of 7,500 ampere-hours. I could add, if need be, many other illustrations of the fact that we are not only users of electrical energy in immense numbers of small units, but we also have some small numbers of large units. I should like the members of the Institution to grasp the fact, and they will no doubt do so from this paper, that the Post Office looks upon electricity as its youngest and sturdiest assistant.

Mr. J. S. HIGHFIELD: I had the pleasure some time ago of being taken by Mr. Gunton over a considerable part of the engineering works of the General Post Office, and I am bound to say that what impressed me most was the point to which reference has already been made, the immense variety and the great range of the work dealt with by the Post Office engineers. One part of the paper which specially interested me was the important question of supplying electricity to the Post Office for general power and lighting purposes. It seems to me that it is far more important to get a perfectly secure supply than one at the lowest cost, since the cost of electricity must be an extremely small proportion of the total operating expenses. I think Mr. Gunton is quite right to have done away with the small local plants, although I do not see why it was necessary to erect a comparatively small station supplying from a distance. The small local plants offered the great advantage of being extremely secure, whereas the high-tension plant now used cannot claim the same security. I think that probably the most efficient and secure supply

that could be provided would be to work from the public mains and use a local battery as a stand-by. It is difficult to see how a failure could then take place. The whole of the paper, it seems to me, illustrates the difficulty of dealing not only with a great number of small machines of different types, but a great number of men. The difficulty always is to get the man and the machine to fit, that is to say, it is necessary to design machines which the men can work; and when there is a great number of men it may be very difficult to get a radical alteration, even a radical improvement, adopted by an exceedingly large staff. In my own experience I have found it necessary gradually to improve the design so as not to go ahead of the man: that is to say, it is necessary to train the men just as fast as the design is improved. If a machine that is known to be better, but which the men cannot be taught to use, is installed, then slower operation obtains. I cannot imagine a better illustration of the difficulty of fitting the man to the machine, and the way in which the characteristics of the men must be taken into account, than the author's reference to clerks and sorters and how the difference in their work is the first consideration in designing the heating apparatus.

Mr. C. H. PERKINS: One of the most useful purposes which this paper serves is to make those of us who are not in the Post Office Engineering Department more fully appreciate the extent of the engineering work carried out by that Department. In some portions of this work, such as street pneumatic tubes and the plant for operating the same, the Post Office are really the only people who have had any considerable recent experience, and it is with reference more particularly to this branch that I propose to make a few remarks. Recently the Eastern Telegraph Company found it necessary to remove their main London telegraph office to Electra House, and to enable us to meet the ever-increasing demands for improved service it was considered advisable, in order to accelerate deliveries in the city area, to connect up by pneumatic tubes various sub-offices with the new main station. Although we had operated a small installation satisfactorily for some ten or twelve years, the proposed scheme was so very much larger in its scope that it was considered desirable to ascertain the latest practice in the Post Office in order that we might have a really up-to-date installation. We now lease from the Post Office a total of 9 street tubes, the longest being that to Mincing Lane (a distance of 1,677 yards), the total length of these tubes being approximately $4\frac{1}{2}$ miles. All these tubes are naturally laid in some of the busiest and most congested streets in the City, and of course the responsibility for the laying of these additional tubes fell solely on the Post Office engineers. It is, however, more in connection with the plant for operating these tubes, and for the provision of which we had made ourselves responsible, that I wish to record our appreciation of the courtesy and advice which we received from the Post Office Engineering Department. This installation consists of three tandem pumps—two similar 60-b.h.p. sets and one 15-b.h.p. set. The total free air capacity of the installation is 1,800 cubic feet per minute—a mere trifle when compared with the G.P.O. West outfit, but considerably larger than the similar installation at even such a large provincial centre as Birmingham; and the accommodation and installation of plant of this nature in the basement of

city offices not designed for the purpose presented some difficulty. Happily so far the whole installation has operated without a hitch—a tribute alike to the Post Office work on the tubes and to the makers of the compressors.

As regards the new Post Office pattern double-slide pneumatic switches, which I have heard are now installed at St. Martin's le Grand also, there are two small faults to which I should like to draw attention. We experience occasional—I almost said fairly frequent, but that scarcely represents the case—breakage of the fronts of the observation and clearing windows. The treated celluloid and mica hitherto employed do not seem to be quite satisfactory. Perhaps the alternation of thinner sheets of both will prove more successful. The other point is the frequency with which the skirt of the carriers is cut away by these switches owing to the somewhat careless and rough handling that must, I fear, be naturally expected from boy attendants. It would be interesting to know whether similar trouble is experienced at St. Martin's le Grand, and, if not, whether anything has been done beyond altering the by-pass or modifying the steel disc which actually does the damage. To illustrate the extent of this damage I would mention that in our recent routine overhaul a bucket-full of small pieces of felt was taken out of our vacuum container. There is one other matter, a small but very important one. Improvements in plant and air switches take place, but the old form of carrier still remains. Perhaps the author will be able to give us a little further information as to the probability of an improved form being available in the near future. Although we have tried other types we have reverted to the old standard G.P.O. carrier, but are very willing to welcome any improvement on this. It is very interesting to note the extension of the use of mechanical conveyors for more elaborate services than those for which they have hitherto been employed. Outside the Post Office service the use of these appliances must of necessity be very limited and on a small scale, but we find that the installation of cord and hand carriers in our London instrument room has been most beneficial in reducing delays and keeping the gangways clear of messenger boys.

Mr. R. T. SMITH: This paper is rather a departure, and to my mind a somewhat welcome departure, from many papers which have been read before this Institution in that it describes machinery driven electrically rather than what may more properly be termed electrical machinery itself. A further interesting point is that the machinery has been designed and specified by the staff who have to maintain it, instead of by engineers whose interest ceases shortly after the maintenance has begun, so that they very rarely have the opportunity of observing and measuring results during maintenance, and so finding out what parts of the design were wrong. Where those who have to maintain machinery which they have specified or designed have the ability and opportunity of making measurements, as is the case in the Post Office, the results are most interesting; and I think that one of the best things in this paper is the set of comparative curves of cost of hydraulic and electric lifts working under the same varying conditions. Those results could only have been obtained by maintenance engineers having very considerable experience extending over years with that class of machinery. To all those who have to decide, or have to help to decide, between the

use of hydraulic power and electricity, the comparative curves of costs given by Mr. Ganton will be useful. The conveyors in the London Post Office building are ingenious and, as has been pointed out before, very varied in purpose and design. With light loads such as occur in Post Office work the energy used for moving the conveyor itself is probably only very slightly increased by the load, most of the energy being used in moving the conveyor. If the author could give us any information on that point I should be glad. When one comes to much bigger conveyors such as are used for carrying coal and minerals, where the energy taken to move the conveyor itself may not amount to 20 per cent of the total energy, the case is different. Such conveyors when raising material from one level to another take the same amount of energy as is taken by a crane, or hoist, or tip to do the same work. The difference between a conveyor and the lift, or the tip, or the crane, is that while in the latter 100 h.p. may be required for one minute, in the former 10 h.p. is required for 10 minutes. From the electrical engineer's point of view it is quite obvious that the conveyor is a very profitable load to supply, as it runs very nearly at 100 per cent load factor while it is working.

The way in which the lighting has been arranged at the Post Office building is a tribute to the usefulness of the measurement of illumination on a horizontal plane, which has been much discussed lately. I should like to ask the author whether the amount of illumination is decided wholly from measurements with the lumeter on a horizontal plane, or whether measurements are also taken on vertical planes. In connection with the electric trucks which have been referred to, the Post Office is in rather a better position than some other users in charging the batteries employed with these vehicles. The trouble with the charging is that various voltages below standard have always to be dealt with, such as 60, 80, and 140 volts, and the great difficulty that I see in the development of the truck, which is otherwise most useful, is the charging of the batteries on any commercial circuit. If there are a great many of them it is easy enough, because one can then afford to have a motor-generator and a man to look after it; but what is wanted for economy in these vehicles is that the ordinary user should be able to plug his cells on to a commercial circuit. The claim for the Jungner and Edison type of battery is that the ordinary user can charge in this way at constant voltage, and if he overcharges he does not do the battery much harm, while if he over-discharges, so long as it is not a short-circuit, the battery is not materially damaged. I should be glad if the author could give us any information as to the arrangements that he makes for charging the comparatively small number of these batteries which the Post Office possesses.

Mr. A. J. STUBBS: The general public, and perhaps even electrical engineers, find it difficult to realize how very widely spread Post Office engineering interests are. Mr. Wordingham has referred to "standardization"; this reminds me that the Post Office Engineering Department is represented on, I think, 9 or 10 of the Committees and Sub-Committees of the Engineering Standards Committee. We furnish a field of training for the Army Telegraph and Telephone Engineers; we touch the Admiralty at several points; we are in close touch with practically all Government Departments on engineering

questions; and, what is perhaps of more particular interest to some members of this Institution, although power users ourselves we have a statutory duty in protecting the huge national plant entrusted to our care against users of power in other branches of electrical engineering. That represents to us a very serious responsibility—how far the strict letter of the Postmaster-General's statutory rights must be enforced, having regard to securing that we shall not, more than is absolutely necessary, hamper expansion of other very important electrical works all over the country. But, of course, as Post Office servants our prime interest in this connection must necessarily be the protection of the huge plant of which we have control.

Mr. A. W. MARSHALL: A previous speaker has referred to the difficulty of the inspection glasses on pneumatic tubes; might I suggest that there is a new glass which has been put on the market, consisting of a sheet of celluloid between two thicknesses of glass. I believe it is now available, and I have a piece which has been deliberately shattered and which still holds together. It is perfectly transparent. The inserted celluloid remains intact. I think possibly this may solve the difficulty that has been mentioned. I understand it is being used in submarines, and that the makers are the Triplex Safety Glass Company.

Mr. E. W. REES: The author has amply demonstrated the wide field covered by the Engineer-in-Chief's Department of the Post Office. The figures quoted on page 112 respecting the power station are very satisfactory. The running load factor (70·2 per cent) and the high overall efficiency (87·4 per cent) are exceedingly good, but compared with them the evaporating factor is not so favourable. There is probably some explanation of this. The curve showing the typical daily load at Blackfriars power station demonstrates how carefully the load had been anticipated with regard to the size of the generating sets installed, which is reflected in the very satisfactory running load factor. I have seen the pneumatic plant, and, although the author does not mention it in his paper, he appears to have adopted after-coolers. It does not seem to me to be a case where these should be employed. Having got the energy into the compressed air, it does not seem good practice deliberately to abstract and waste it. I estimate that the loss from this must be something like 16 per cent of the total work done in the pumps. When the air is further expanded in the street tubes saturation may occur under certain atmospheric conditions, with the result that moisture is deposited in the tubes, the speed of the carrier in the tube is decreased, and the loss due to leakage is increased. I suggest for Mr. Guntton's consideration the possibility of cooling the air below freezing-point by means of brine pipes in the vacuum containers. If at all feasible this would increase the weight capacity of the pumps by about 15 per cent, and would dry the air and so prevent deposition of suspended moisture in the street tubes. Indeed, it would effectively dry out any moisture which might get into the tubes from extraneous sources. From a rough calculation it appears to me that a 60-h.p. refrigerating plant would cope with the air dealt with by all the compressors, and this would represent a loss of about 7 per cent, resulting in a net gain of, say, 8 per cent in the useful output of the plant. The method of pumping adopted by the author is extremely useful

where pumps show excessive valve losses due to defective design. As regards the lifts, the curves given in the paper are exceedingly useful, but they seem to require some slight modification: for instance, 6 per cent on the capital cost is allowed for interest and depreciation. This figure seems much too low: it might apply to a direct-acting hydraulic lift, but not to an electric lift. I consider that even a suspended hydraulic lift should be debited with a smaller amount on account of depreciation than an electric lift. In short, I think the point of intersection of the lines referring to hydraulic and electric lifts of similar size should be moved more to the right in Fig. 6, and the curve in Fig. 7 should be drawn higher up. As regards safety, I think every safety appliance which can be applied to an electric lift can now be applied to an hydraulic lift. I also consider that the hydraulic lift still holds the field as regards reliability.

Passing to electric lighting the author advocates general lighting under three sub-heads (page 120). In regard to (1), perhaps he will tell us what is his basis of comparison as regards the absence of shadow and eye-strain. In respect to (2), is not the extra cost of lamps in individual lighting set off by the extra cost of energy in the case of general lighting? As to (3), it is thought that the convenience of moving sorting fittings without producing shadows would be more effectively met by making the lighting fitting an integral part of the sorting fitting. Letter sorters have to decipher at the rate of 60 per minute addresses written in all kinds of handwriting on various coloured paper with various coloured ink, and I do not think the illumination provided is sufficient to meet this condition. If a man has a 30-watt lamp under a 9-in. shade just over him, he can increase the illumination on an indistinctly addressed letter through a wide range, which is not possible in the case of the form of lighting advocated by the author.

Mr. C. A. BAKER (*communicated*): The author will perhaps in his final reply explain the considerations which the Post Office Engineering Department had in view when it was decided to erect a generating station for the supply of electrical energy in the London area. During the discussion of this paper the Chief Engineer of the Post Office made a statement to the effect that his Department "does not manufacture anything that can be bought." The main item of interest to this Institution which could possibly come within the category of Mr. Slingo's statement is electrical energy, and surely this can be bought in London in any quantity that the Post Office might require. The Blackfriars generating station is on the south side of the river; the cost of the energy with a 73 per cent load factor is stated to be 13d. per unit. On the north side of the river I can buy electrical energy, on a load-factor basis of about 50 per cent for public lighting at a price, which is no secret, of 1d. per unit; while in another part of London, with a load factor of about 75 per cent, I am able to buy at an average price of 0·06d. per unit. Within the last few years it has been possible to close down two generating stations which were previously supplying the demands above indicated, with resulting economies of £700 and £1,000 per annum respectively. The misfortune of having so many small generating stations in London was emphasized in Dr. Klingenberg's recent address before this Institution,¹ but of course it was not then presented as

¹ *Journal I.E.E.*, p. 123, No. 225.

er. a new fact. Perhaps, however, reasons of policy rather than of engineering decided the establishment of the generating works, and any information which the author can supply on this point will be of great interest.

Mr. H. C. GUSTON (*in reply*): With regard to Major O'Meara's remarks, I am particularly glad that he has given me an opportunity of acknowledging the encouragement which he gave me soon after I came to the Post Office, and it is very largely due to the suggestions that he made on his return from America that some of the appliances with which we have been experimenting have been followed up.

Mr. Wordingham dealt first with the question of standardization. We are doing everything we possibly can to standardize such parts of our apparatus as lend themselves to standardization. It is of course very difficult, as Mr. Wordingham himself has realized, because the designs of a number of different firms have to be considered, and we do not want to reduce competition; in the case of conveying appliances it is particularly difficult. In the case of lifts there is not so much the difficulty of differences in design, but there are still the different forms of supply to contend with. What we do in order to arrive at standardization, so far as it is possible, is to sectionalize the specification: that is to say, we have one part of the specification dealing with the general arrangement and points which vary in almost every case, and another part made up of standard clauses and leaflets. For instance, we have a standard leaflet for the three-phase motor, another for the continuous-current motor, and so on. By the use of these standard clauses and leaflets a specification can be built up with a minimum of labour.

With regard to the possibility of danger when our battery automatically takes charge and keeps up the extra-high-tension supply, I may say that any danger is guarded against by the fact that telephonic communication is established as soon as anything occurs to upset normal conditions, and that any such upset, whether in the form of trouble with a turbo set or a breakdown on the transmission system, would be evident both at the power station and at the sub-station from the behaviour of the plant and the indications of the instruments. Moreover, no circuit is ever assumed to be "dead" until certain precautions have been taken in accordance with stringent regulations.

We have at intervals gone very carefully into the question of introducing electric cooking, and generally I may say that with the prices at which we can buy electricity at present we have not so far been able to make out a commercial case for it. We should be very glad to be able to do so, because it is undoubtedly a much more cleanly and convenient form of heating.

As to electric and hydraulic lifts, and the question of efficiency, first cost, and reliability of the different supplies; so far as three-phase or two-phase alternating-current supply as compared with continuous-current supply is concerned there is not very much in it. Any very slight difference in the efficiency of the motors and control is quite outweighed, as a rule, by differences in the efficiency of the gearing; in this connection I might say that we purposely use low-efficiency gearing to a large extent in order to increase the safety of the installation, and when we install high-efficiency gears we have always supplemented them by emergency brakes, so that if the lift tends

to run away there is a ready means at hand for applying a Mr. GUNTON brake. A single-phase supply is much less desirable both as regards efficiency and reliability.

With regard to the system of ventilation, it is usual to use an extractor fan of the propeller or centrifugal type and to admit the air at a suitable height, warming it by means of the radiators. The propeller type is the more efficient where there is a free inlet and outlet. We have been careful to apply ozone in small quantities only, when it has certainly appeared to be harmless and to have a refreshing effect. In large quantities I agree that it might be harmful.

I do not think I need say anything in regard to Mr. Slingo's remarks, as what he said was an extension and amplification of what I have said in my paper.

In reply to Mr. Highfield, I quite agree with what he said as to the importance of security. He referred to the comparative reliability of the self-contained station; that is to say, the station in the basement of the Post Office as compared with having a supply from a distance. I may say that we have been forced, and are being forced, to give up these small stations. We have to find room for considerably more power now, and as a rule we could not extend the plant in the space available. Moreover, a power house in the basement of a building in which a lot of men are employed is not, from a purely humanitarian point of view, a very desirable installation. It tends to vitiate the air of the whole building, and I know that post-masters in provincial towns are generally very glad that we have been able to make a case, and an economical case, for shutting down these steam generating stations. I was particularly glad to hear what Mr. Highfield said as regards the safety provided by the batteries, although I cannot agree that the supply from our own outside station in conjunction with a battery is less secure than a supply from public mains in conjunction with a battery, the former being the arrangement adopted in London and the latter at certain of the larger provincial towns. Personally I should be very sorry to be without the knowledge that we have a battery in one of our sub-stations at the General Post Office, and we do not sacrifice efficiency seriously by introducing them. He also referred to the difficulty of training the men to use new appliances. It is certainly a very big undertaking to introduce any labour-saving device into an establishment in which a large number of men are employed. It is wonderful how helpful they are in trying to make apparatus work, but of course they naturally have somewhat conservative ideas, and patience is required to get them used to new ideas. One great difficulty is the fact to which Mr. Highfield has referred, that with any new invention involving a change of method the process must be slowed up temporarily. Take the case of the sorting-office conveyers. In introducing these the idea was to get rid of the human labour involved in carrying the letters; that is to say, if we can send a letter from one process mechanically to the next process, we not only avoid delay but there is no need for messengers to go round to different points and collect the letters by hand. At first what is saved by eliminating those intervals is discounted by the slower rate of facing and sorting under the new process. For instance, if a man has been used to take up letters and arrange them in his hand in a certain way and put them on a shelf, he does not at once get into

the way of taking them up in both hands and putting them in a slot in the table. But as soon as the men get back to what was the normal rate under the old conditions the effect of the improved method of transportation between the processes begins to be felt.

Mr. Perkins has referred to his experience with a new pneumatic switch. We have not had any great amount of trouble owing to the breakage of the windows, but the Eastern Telegraph Company's installation was one of the first which was put in on a large scale, and the experience which Mr. Perkins has had with this installation has drawn our attention to this particular point of weakness. We have altered the design of the window so as to allow of the use of flat glass instead of curved mica or celluloid, and by this means we hope to overcome the difficulty. This also replies to the suggestion kindly made by Mr. Marshall. I sympathize with Mr. Perkins's endeavours in trying to evolve a new form of carrier; we are continually experimenting with new forms of carrier in order to effect improvements. We are trying leather carriers very largely, but it is somewhat difficult to get sufficient flexibility in the head of the carrier so that it will adapt itself to the tube at all points. If these carriers (which have no skirts) can be adopted they will provide a means of overcoming the difficulty in connection with the operation of the new switch.

Mr. Roger Smith referred to the importance of measurements, and I quite agree with what he said. If we are going to learn the maximum that is to be learned from the plant we are using, we must systematically measure.

The amount of energy required in driving conveyers varies so much with different installations that I should not attempt to evolve any formulae which would represent the power required: it depends on the material used for the band, and the material used for the band necessarily depends upon the character of the load to be carried. The power is also affected by deviations in the route, and I should say at once that the power required to drive various kinds and arrangements of conveyers can only be arrived at through actual experience. With the comparatively light loads with which we have to deal, the additional power to drive the conveyer loaded, compared with that to drive it light, does not usually exceed 15 per cent. The continuous availability of the conveyer from the user's point of view, combined with its high load factor from the supply point of view, should undoubtedly make it a popular contrivance as compared with the lift, as indeed is illustrated by the introduction of the escalator.

The decision which has been come to as to the amount of light to be given is the result of measurements in the horizontal plane at the level at which the work is actually carried out.

With regard to the difficulty of charging batteries on vehicles we are better placed in that respect than most commercial concerns would be. We have power in the form of low voltages available at most of our centres, and we also have the necessary staff to attend to any motor-generators which it might be convenient to provide for this purpose. Mr. Roger Smith spoke rather as if we had a fleet of these trucks, but we are only experimenting with the first at present; so far with very satisfactory results.

Mr. Stubbs dealt with general considerations, and I

think I need not say anything with regard to his contribution to the discussion.

Mr. Gant

I was particularly interested in Mr. Rees's remarks, because he was at one time associated very closely with some of the work which he has subjected to friendly criticism. With regard to the low evaporation figure, this was due to poor quality of coal at the time, and was quite temporary. With regard to the use of after-coolers in connection with our pneumatic sets, we have to take a very large view of these matters. If we pumped hot air into our instrument rooms there would be trouble in the summer-time. We have not tried refrigerating plant in the vacuum containers, and I do not think the further complication would be justified, especially as insufficient reduction of the delivery temperature would be obtained. Moreover, the cooling should only be applied to the air compressed, which can only be achieved on the delivery side with the method of regulation employed in connection with this system of "pumping through." Further, the after-coolers not only reduce the condensation in the system of tubes but provide a convenient means of collecting any oil delivered with the air. Mr. Rees also suggested that this "pumping through" system might be introduced in other places where there was room for improvement in the efficiency of the sets. It certainly improves the efficiency of working, and it was due to an investigation by Mr. Rees that the system of pumping through was introduced. He pointed out that although there was a slight percentage of loss in connection with the compression, this was more than counterbalanced by the elimination of the additional plant and valves which it is necessary to employ when separate pumps are used for pressure and vacuum working, and the gain in space is considerable. On the other hand, disadvantages, to which I have referred, are at the same time introduced, there is a much higher temperature of the air delivered, and there is also the danger of drawing in gas in the event of there being any leaks in the street tubes. Of course there should not be any leaks in pneumatic tubes in the streets; but some of our tubes have been laid for something like 40 years, and some of the joints are not altogether perfect. Even if gas is drawn in and an explosive mixture is obtained, an explosion does not necessarily result, but the condition is of course dangerous. We have guarded against this by sampling the air drawn into the vacuum system, and testing for gas; we have also safety devices in the form of explosion valves, so that the effect of any explosion would be minimized.

With regard to Mr. Rees's criticism of the allowance of 6 per cent for capital charges in connection with Figs. 6 and 7, I do not consider that the allowance need be any greater for an electric lift, as compared with an hydraulic lift; as regards the actual percentage adopted, it is of course easy for anybody using these curves to make any necessary adjustment to suit their own allowances, and it was for this reason that the actual figure used was stated. As a matter of fact we should now allow 8 per cent in each case owing to the recent adoption of a more conservative basis for the life of the plant. It is not considered that the cost of maintenance of an electric lift is, generally speaking, more, or the reliability less, than that of an hydraulic lift.

With regard to the question of fittings and lights,

generally speaking I think my contention is correct, that with the system of general lighting we are more or less independent of fittings; and that is a particularly valuable point if light is being provided in a new office under conditions of urgency; that is to say, the lighting installation can be proceeded with and get ready without waiting for the supply of the sorting fittings.

My reference to comparative absence of shadow and eye-strain was in comparison with arc lighting and lighting by individual lamps on the fittings in close proximity to the sorters' eyes. The new method was adopted after careful experiments, and has been generally accepted as the most suitable method of lighting large sorting offices, instrument rooms, and public offices.

MANCHESTER LOCAL SECTION, 16TH DECEMBER, 1913.

Mr. W. J. MEDLYN: The subject of this paper is not one with which Post Office engineers usually deal, our business being more generally concerned with telegraphs and telephones, and the lighter side of electrical engineering. The author refers to the difficulty caused by condensation of moisture in pneumatic tubes under the streets. We have had a considerable amount of difficulty in this connection with one particular tube at Liverpool, which is in almost continuous use throughout the day; the air is forced in at a temperature of 60° to 70° F., and unfortunately when it cools moisture is formed in the tubes, causing the messages and carriers to become damp. It is therefore important that the air forced through the tubes should be at a low temperature. On page 112 mention is made of the difficulties caused by gas leaking into the tubes. We had a case of this kind in Liverpool where there was a leaky gas main, and also a leaky cast-iron pipe over the lead pneumatic tube, and about 200 yards away there was a leak in the tube itself; the gas was drawn into the tube by means of the vacuum and turned into the containers at the post office. Fortunately the defect was discovered in good time, or the containers might have been transformed into miniature gasometers liable to cause an explosion. The author has not said very much on the question of power supply for telephone exchange equipments. This is a matter which is of considerable interest to Post Office engineers. In the South Lancashire district we have, in the aggregate, a fairly large installation of accumulators varying from 40-ampere-hour capacity to 6,000-ampere-hour capacity. Altogether there are about 64 telephone exchanges and over 30 of these are fitted with accumulators. The total consumption of energy for charging purposes amounts to approximately 200,000 units per annum. Many of the exchanges are of the magneto pattern and will ultimately be converted to "common battery" working, so that the energy consumption will be considerably increased. The author refers to the adoption of a reasonable standard of general lighting. Prior to the introduction of the present system we had a considerable number of complaints from the staff generally, but I am pleased to say that since the system of general lighting was introduced many of our worries in this respect have disappeared.

Mr. G. H. VAUGHAN: Mr. Medlyn has referred to the inconvenience caused by moisture in pneumatic tubes, apparently due to condensation. Perhaps it will be of

With regard to the suggested low illumination, if we do not give our sorters enough light we very soon hear about it. We do not want to give them more than is necessary, and the illumination at present is generally giving satisfaction. If we got complaints on a large scale which were considered justified we should of course seek authority to increase the amount of illumination.

In reply to Mr. Baker's communicated remarks, I may say that the decision to generate our own electrical energy for the General Post Office was only arrived at after carefully considering the price which would have to be paid for it from an outside source in the form in which we required it and having due regard to the all-important consideration of reliability.

interest to mention that a pneumatic tube ticket-distributing plant was installed in the London Trunk Exchange, of which I had charge, and it was essential in order to ensure satisfactory working that the tickets, which were folded in a certain manner, should be perfectly rigid, and also that the tube, which was of rectangular shape, should be free from moisture. The rigidity of the tickets was effected by placing them in an electrical oven and thus extracting all the moisture. In order to eliminate the trouble due to moisture or condensation in the tubes, I suggested that a series of cylinders with closely fitting bags containing calcium chloride should be placed in series between the dash-pot valve and the air container in order to ensure that only thoroughly dried air should enter the tubes. The adoption of this device is, I believe, under consideration. Owing to the well-known hygro-metric condition of the Manchester atmosphere it would not be possible to adopt the pneumatic tube ticket distribution system in Manchester unless some such means were adopted.

Professor E. W. MARCHANT: There are two points I should like to raise in reference to this paper. The first is with regard to the author's statements as to the improvements in efficiency which he has been able to obtain in the starting of the motors. If a motor, in which the flux per pole is constant, is running on constant-pressure mains, no matter how the current is varied during the process of acceleration the total energy taken from the mains for accelerating the motor is constant. The torque exerted by a motor is proportional to the "accelerating" current. If I be the total current taken, at a pressure V volts, I_f the friction current, and I_a the accelerating current, then $I = I_f + I_a$. The accelerating torque $F_a = k I_a$, where k is a constant depending on the motor. The rate of increase of speed depends on the torque and on the moment of inertia of the moving system.

We may write $k \frac{d n}{d t} = F_a$, where k' is a constant depending on the moment of inertia.

Hence $k' \frac{d n}{d t} = k I_a$. Integrating this equation from speed 0 to speed N , we get $k' \int_0^N d n = k \int_0^T I_a d t$.

Now $\int_0^T I_a d t$ is the total quantity of electricity taken from

Mr. Gunton.

Mr. Vaughan.

Professor Marchant.

Professor
Marchant.

the mains to accelerate the motor from speed 0 to speed N . It follows from this, that if the current supplied is taken from constant-pressure mains, the total energy used in accelerating will be proportional to N , the final speed attained. It makes no difference in the total energy consumed whether the rate of acceleration is small or large, uniform or variable. In this calculation the friction current has been left out of account, but if, as is the case with a lift, this current is comparatively large during the period of starting, it is better to state the result as follows. $I_s = I - I_f$, as above. Hence—

$$k \int_0^N dn = k \int_0^T dt - k \int_0^T I_f dt.$$

$\int_0^T I dt$ is the total quantity of electricity used = Q , say.

I_f in most cases is nearly constant. Hence—

$$k N = k Q - k I_f T.$$

where T is the time taken in starting. Hence—

$$k Q = k N + k I_f T.$$

From this it is clear that the total quantity of electricity used during the energy of acceleration will be greater, the larger the value of T , i.e. the longer the period of acceleration lasts.

The more rapidly the acceleration is carried out the less the waste in power will be. The results which the author has obtained with shunt motors must therefore be due to the shorter time taken in accelerating the system. With regard to the term used on the last page of the paper, namely, "electric truck," I hope the author will change this to "electric battery truck." The term "electric truck" might be applied to any form of electrically-driven vehicle, whereas this term applies to a battery-driven vehicle.

Mr. H. C. GUXON (*in reply*): Mr. Medlyn has referred to moisture in tubes, and I might say that it is for this reason that pneumatic tubes for street work are carried

out in lead and for housework in brass. With regard to the danger of explosion from gas, I hope I have not been unduly pessimistic in what I have said. Even if gas of a critical mixture is drawn in, it is still necessary to ignite it before there is an explosion, but it is of course advisable to keep the tubes as free as possible from gas. With regard to telephone exchange equipments, I did not deal with these very fully because they come more under the category of telephone and telegraph engineering than under power engineering.

Referring to Mr. Vaughan's remarks on the drying of air; we are at present experimenting with a view to preventing condensation.

Professor Marchant has dealt with the mathematical aspect of the lift motor. Lift-motor control, however, is very like electric tramway or electric railway control. The pressure is applied to the armature through a series of steps of resistances, and it is these resistances which may unnecessarily waste the power. Some years ago I was engaged on the starting up of an electric railway in London, and we noticed that the consumption of energy from the sub-stations was very much more than corresponded with the consumption of energy that we had previously measured on the trains, even allowing for the losses in the conductor rails and other unavoidable losses, and I found that the drivers were lingering over the operation of the controller. We got them to speed-up the "switching on," and the consumption of energy was considerably reduced; we have effected the saving in lift operation in a similar manner. By speeding-up the controller we are still using the resistances to keep the current within bounds, but we are not lingering too long on one step and then having to accelerate on the next step. What we aim at in the operation of controllers, whether by means of a human driver or by a remote control arrangement, is to maintain the accelerating current at its right value and not to let it decrease.

While I think the term "electric truck" as applied to a truck used between a sorting office and a railway platform suggests a self-contained equipment, I quite agree that "electric battery vehicle" is preferable to "electric vehicle" as a general description of vehicles equipped with batteries.

Mr.
Guntton.

DISCUSSION ON

"THE BRITISH STANDARD SPECIFICATION FOR CONSUMERS' ELECTRIC SUPPLY METERS."*

YORKSHIRE LOCAL SECTION, 10TH DECEMBER, 1913.

Mr. T. ROLES: I am in agreement with the author's introductory remarks, and his remarks with regard to Clause 2.

Clause 3.—Where strength and shielding from external fields are the main considerations, as in continuous-current work, it is undoubtedly an advantage to have cases made of cast iron or pressed steel, but in the testing of alternating-current meters, especially where adjustments are required, it is often found convenient to have cases of non-magnetic metal, as the meters can then be calibrated without having to replace the cover after making each adjustment. It is also advisable to have meters of comparatively light weight, consistent with reasonable strength and rigidity. This is particularly the case when the instruments have to be carried by hand. Meters with cases which appear to be mechanically strong are invariably subjected to rougher treatment than instruments fitted with light cases. Alternating-current meters having non-magnetic and light metal cases, provided the latter are reasonably able to withstand mechanical injury, are in some instances preferable to meters fitted with cast iron or pressed steel cases.

Clause 6.—The proposed alterations to this clause are urgently necessary; the terminal box and holes should be ample, as suggested. It is often the case that manufacturers do not sufficiently consider the matter from the point of view of those who have to fix the instruments. It would greatly facilitate the connecting up of meters if a uniform system of marking the terminals were adopted. Some makers paste a diagram of connections on the inner side of the terminal-box lid, and in such cases a person of average intelligence experiences little difficulty in making the correct connections. It would, however, be a great convenience if all terminal blocks were clearly marked according to an agreed system. The author does not make it clear whether the holes he mentions are for the copper wire only or for the insulated cable. Terminal lugs should certainly be provided for meters over a certain size, say 50 amperes, it being obvious that a good connection cannot be obtained by the use of two clamping screws where a 500-ampere cable is being brought in, with a hole 1 in. in diameter by 2 in. long. Further, the use of terminal lugs often gets over the difficulty which is experienced in coupling up a small circuit of, say, 3/20 S.W.G. with a cable of very much larger capacity.

Clause 10.—The author's suggestions for modifications of this clause are excellent. My experience is that where the meter cases have to be drilled, however carefully the work is done, particles of iron cling to the magnets and are very difficult to remove without impairing the strength of the brake magnets; in fact, the removal of such particles often necessitates the re-adjustment of the instruments. The manufacturer could drill these holes before the meter was assembled. The size of the owner's

labels, as stated in the specification, is on the small side, Mr. Roles. the labels in use in Bradford being $\frac{3}{4}$ in. by $1\frac{1}{2}$ in.

Clause 11.—I agree with the proposed alterations to this clause. The success of the cyclometer dial depends largely on its being readable without any possibility of error. Difficulty is frequently experienced, however, in ascertaining the correct reading, and we have found many inaccurate records to be due to inefficient cyclometer dials; so much so, that for the present we are refraining from ordering meters with dials of this type.

Clause 12.—In my opinion the term "kilowatt-hour" is preferable to that of "unit." Has the author considered using the term "kelvin"?

Clause 16.—I share the author's opinion that there should be definite figures as to the permissible losses in the main circuits of meters of various sizes.

Clause 17.—I agree that the clause should differentiate between the permissible pressure-circuit losses in continuous-current and alternating-current meters. It is, however, a debatable point whether a reduction in the pressure-coil losses in meters should be obtained at the expense of the meter torque. Four watts per 100 volts is, however, a high figure for alternating-current single-phase meters, and could easily be reduced to two watts for any pressure usually met with in practice.

Clause 19.—I agree with the author in regard to the suggested revision of this clause. A starting current of 0.5 per cent seems to be a fair figure and should be expressly stipulated in the specification.

Clause 20.—The permissible errors in meters from full load to 1/20th of full load should certainly be reduced to at least 2.5 per cent over the whole of this range except for instruments smaller than the 10-ampere size. With due allowance for temperature variation there is no reason why the error should exceed the above limit.

I regret that the author has not taken up the question of the insulating material to be used in meters. In my opinion no ebonite whatever should be employed for insulating purposes. The main insulation should consist solely of mica and steatite, and the use of press-palm should be restricted to positions where there is little or no pressure. I have received for test purposes instruments in which ebonite and press-palm have constituted the main insulation. Trouble has, however, been experienced until insulation of a more stable type was employed. Where moulded insulators are used for the terminal blocks, these should be of a standard pattern and composed of material of approved insulating qualities capable of withstanding high temperatures.

Clause 14.—Another point not dealt with in the paper is the question of speed, that laid down in the specification, namely, 150 revs. per minute, being in my opinion excessive. The speed of the rotor should not be greater than can comfortably be counted, and it would greatly facilitate

* Paper by Mr. S. H. Holden (see p. 39, No. 223).

Mr. Roles

the work of testing meters and farther eliminate friction in the bottom bearings if it were stipulated that the rotor speed should not exceed 80 revs. per minute and that any speed adopted should be a multiple of 20. The question of constants might also have been touched upon by the author. I am firmly of opinion that the gearing between the rotors and the dials of meters of the same make and size should be uniform. In Chamberlain & Hookham and Ferranti continuous-current meters, after the work of assembling is completed, the speed of the rotor is ascertained and a ratio wheel then inserted so as to obtain the correct reading on the dial. B.T.H. mercury-motor meters are, however, made with a fixed ratio between the speed of the rotor and the dial, and it should be possible for the makers of other types of instruments to adopt the same principle. The use of wheels having different ratios in the same make and size of meter should be abolished, as the use of these frequently leads to confusion when instruments are being tested.

Mr. Fedden.

Mr. S. E. FEDDEN: It is quite time that the British Standard Specification should be extended so as to include meters which are used in conjunction with potential and current transformers; such meters are now always used on high-tension and extra-high-tension supplies.

Clause 6.—It is very important that meters should be provided with substantial terminals, and sizes above 50 amperes should be provided with sweating sockets. A common trouble is that sufficient metal is not provided in the terminal block for the screws, and the thread is easily stripped.

Clause 12.—The term "unit" is no doubt better than "kilowatt-hour," as it is always used in connection with the sale of electricity, and is therefore better understood by consumers.

Clause 17.—I consider the limit of 4 watts for each 100 volts of pressure in the potential circuit is far too high; $1\frac{1}{2}$ watts per 100 volts is quite sufficient. It is to be hoped that when the appendix to the specification is published it will deal with the method of calculating the error of a meter so that the percentage of error will be calculated on a uniform principle. The method of carrying out tests on single and polyphase meters should also be standardized.

Mr. James

Mr. S. JAMES: On page 41 the author refers to Clauses 25, 26, and 27, and points out that they are not sufficiently definite. The specification does not mention the limit of error when all the three variations mentioned in these clauses are taken together. It may therefore be inferred that if a meter which is $2\frac{1}{2}$ per cent fast under normal conditions is tested at 0.5 power factor with a 10 per cent increase or decrease in voltage and a 5 per cent increase or decrease in frequency, the meter will still be acceptable if the total error does not exceed $6\frac{1}{2}$ per cent should all the errors be cumulative. Probably this was not intended when the specification was drawn up. The author suggests that the words "shall not cause an error" should be altered to "shall not increase an error." I do not consider that this alteration will have the desired effect. For example, a meter may be $\frac{1}{2}$ per cent fast and a variation of 10 per cent in the pressure may increase the error by 1.1 per cent, making a total of 1.6 per cent. The meter would still be within the $2\frac{1}{2}$ per cent limit permitted, but must be rejected nevertheless. I suggest that the words "shall not cause

an error in respect of such variation of more than Mr. James' 1 per cent" be altered to "shall not cause the total error of the meter to exceed $\pm 3\frac{1}{2}$ per cent." I also suggest that the following clause be inserted: "When a meter has a pressure coil and is intended for use on an alternating-current circuit a variation of 10 per cent above or below the marked pressure, and of 5 per cent above or below the normal frequency, at any power factor between unity and 0.5 shall not cause the total error of the meter to exceed $4\frac{1}{2}$ per cent." I mention $4\frac{1}{2}$ per cent because this is the limit allowed by Clause 27.

Clause 26 is not complete without some reference to the power factor at which the test is made. Presumably unity power factor is intended, and practically all good modern meters would comply with this clause under this condition. It does not follow, however, that they will be equally good on a low power factor, as many meters of the induction type are more sensitive to changes of frequency on inductive loads than on non-inductive loads. I do not agree with the author's suggestion with regard to testing dials. If this were adopted, difficulties would arise in large meters running at low speeds. Meters are obtainable which run at 20 revs. per min. at full load, and in a 200-kw. meter the disc would only make 6 revolutions for each revolution of the testing hand. The Canadian Department of Inland Revenue has recently issued an order with reference to the provision of testing dials on meters for sale in Canada, which reads as follows: "Each energy meter must be equipped with a register having at least one dial that will occupy not more than two hours to make a complete revolution when the meter is recording accurately at full load. This dial to be either one of those actually read in computing the amount of energy used by the purchaser, or may be separate therefrom in the shape of a test dial at the maker's option." This is, I consider, sufficient for all practical purposes, as, generally speaking, it is only necessary to take dial readings for the purpose of checking the accuracy of the gearings, and this is usually done on full load. More accurate readings may be obtained by stop-watch tests on all the other loads.

An insulation test with an alternating pressure of 1,500 to 2,000 volts between the windings and the case is in my opinion more reliable, wherever an alternating-current supply is available, than the test specified in Clause 18. Meters which would pass the test when tested with a Megger or similar instrument will frequently break down when operating on a 500-volt alternating-current circuit. Had they been subjected to a 1,500-volt flash test, the weak points would have been at once revealed, and I believe it is the general practice with manufacturers to subject the parts of meters, both before and after assembling, to a test of this description. Continuous-current watt-hour-meters of the commutator type, although not used extensively in this country, should be mentioned, as they suffer from defects peculiar to themselves. For instance, they are easily affected by stray fields, particularly at low loads. If a meter is tested in such a manner that the earth's field assists the main field, a difference of 6 per cent at $\frac{1}{2}$ full load may be observed in some meters when turned through an angle of 180 degrees. This is due to the opposition of the earth's field in the latter case. A similar error may be observed in a meter which is first tested on the positive main and afterwards on the negative. The error may be due partly to

the earth's field and partly to the stray field from the brake magnets, assisting rotation in the one case and opposing rotation in the other. If the brake magnets are shielded by an iron screen, the screen itself may become magnetized, and after a heavy short-circuit on a meter of this description, errors exceeding 30 per cent at $\frac{1}{2}$ % full load have been observed. In view of these facts I think it desirable that some clause be inserted fixing a limit to the error caused by reversing the current in the main and shunt coils and to the effect of the earth's field or stray fields of a certain definite strength.

Finally I should like to add a few remarks concerning polyphase meters. All such meters, I believe without exception, give different readings according to the way in which they are connected to the 3-phase supply. If the mains enter in the order, say, 1-2-3, and a set of readings be taken, these will be found to differ from the readings obtained when the mains enter in the order 1-3-2. The difference between the readings will not exceed 1-1½ per cent in good meters, of which there are a few, but in some meters of Continental origin differences of 7 per cent are not at all uncommon. This renders it essential to test on a 3-phase circuit; moreover the meter must be connected on circuit so that the direction of phase rotation is the same as when tested in the test-room. It is desirable that some limit should be fixed to these errors; 1½ per cent would appear to be a reasonable figure. This trouble might be prevented to a great extent if all manufacturers adopted the convention suggested by the National Physical Laboratory some two years ago with regard to the connecting up of polyphase meters and the marking of the terminals. Purchasers would then be able to connect their meters with the same direction of phase rotation as when the meters were tested in the manufacturer's test-room, thus eliminating the error due to reversed phase sequence. Due to the increasing use of a high-tension supply and heavy currents large numbers of series and potential transformers are called for; the various tests with which these accessories should comply ought certainly to be included in the specification in the near future.

Mr. H. A. NEVILL: I quite agree that, at least so far as alternating-current meters are concerned, the Standard Specification requires several alterations.

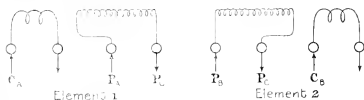

Clause 6.—In addition to other suggestions that have been made it would in my opinion be of considerable advantage to have the arrangement of the main and shunt connections on alternating-current meters standardized. At the present time each maker appears to have his own particular scheme, and when special meter-fixers cannot always be employed this leads to confusion, and wrong connections are occasionally made. It would also be an advantage to have the position of the terminal box the same in all cases, as at present a change in the make of meter installed frequently means alterations to the connections.

Clause 10.—This clause provides for the fixing of a label belonging to the purchaser, but as far as my experience goes this provision is not generally made except in the case of one make of foreign meters. In my opinion the provision of two holes in the meter case is very bad, as all supply authorities do not, I think, affix labels. Holes in the case of a meter are a temptation to tamper with its working. I suggest that a better pro-

vision would be two small rivets ready fixed to attach the label; or even better still, to delete this provision altogether and leave the purchaser to make his own arrangements, as the size of label in use varies so largely. I prefer the Corporation labels to be fixed to the cover of the terminal box.

Clause 11.—The author's suggestion for an addition to this clause to provide a jumping cyclometer figure is very good, as it would eliminate the errors in reading which are so frequent where the meter readers are not always the same. This latter remark of course applies more to small systems than to large ones, where a regular staff of meter men are employed. The suggestions relating to the drop in pressure and meter losses are also good; for as far as alternating-current meters are concerned the specification figures are unnecessarily high. Vibration is a great factor in the maintenance of accuracy in the commercial use of meters, and is also a possible cause of creeping. Unfortunately the results of vibration are more commonly found on a consumer's premises than in the test-room.

Mr. R. M. LONGMAN: A standard specification is very desirable, but the present one is very narrow and of very little use, and is hardly used or recognized by anybody. It should be re-arranged and subdivided. First, general rules and observations common to all; then a classification into (1) continuous-current, ampere-hour, and watt-hour meters; (2) alternating-current single-phase and polyphase meters, and (3) current and pressure transformers. Terminals, their size, number, and arrangement, sadly need standardizing, and also the direction of rotation of the armature or disc—which must be clearly visible with the cover on. All meters should rotate in one direction, i.e. from left to right when facing the meter, or counter-clockwise when looking down on it, and the terminals should

be arranged with the incoming or line terminals on the left-hand side, and the outgoing or load ones on the right-hand side, so that the direction of the current through the meter is the same as the direction of rotation, viz. left to right. A large number of mistakes, leading to reversals and short-circuits, have been caused by the many different arrangements of terminals. For watt-hour meters separate terminals should be provided for both ends of the pressure coil, whether arrangements be made to connect one of them to the current lead or not. For three-phase meters without current or pressure transformers the phases should be kept as separate from each other as possible; for instance, A phase in and out, B phase in and out, C phase in and out, should be the order of the terminals. I have had many cases of flashing-over due to lightning effects, etc., in the meter between terminals of different phases only $\frac{1}{4}$ in. apart. There is no need for much insulation between the terminals of any one phase, but a maximum amount should be allowed between the different phases. Polyphase meters with current transformers should have

Mr.
Longman.

8 terminals, *i.e.* separate current and pressure terminals, arranged as in the diagram on page 213.

There should be no potential difference exceeding 500 volts, alternating or continuous, on any meter; thus on a continuous-current meter for more than 500 volts an external resistance box should be used, and potential transformers, auto-transformers, or external choking coils on any alternating-current circuit having a pressure exceeding 500 volts. The maximum current through any alternating-current meter should be 100 amperes; and even that is a fairly high figure. I do not consider porcelain a satisfactory material for terminal insulation; it is easily cracked, and the cement used to hold the metal part is often a source of weakness. Two screws should always be provided per terminal, and a greater depth of metal must be given so as to give the screws a better chance of holding—in very many cases only a few screw threads are provided, and these are soon stripped.

I certainly agree with the author that cases should be of cast iron or pressed steel, but I think moulded glass should be allowed to stand, as many makers use it for export trade. Many of the thin sheet-metal cases are far too weak, often badly held in position and by no means dust-tight. Further, an iron or steel case is a protection from stray fields—even if it does necessitate the removal and refixing of the cover for every adjustment to the meter. In heavy alternating-current work stray fields must not be neglected. This question of magnetic fields should also be included in the specification, possibly as follows:—A conductor carrying a current of 2,000 amperes, continuous or alternating, and placed in any position at a distance of 1 ft. from the centre of the meter, should not affect its accuracy by more than 0.5 per cent. There should be 5 dials, the value of the first dial division depending on the capacity of each meter. Decimal dials should be painted red. The dial train, cyclometer or clock type, should be in a straight line and as near the glass as possible. I prefer the clock type of dial.

Clauses 16 and 17 certainly require revision on the lines suggested by the author; 4 watts per 100 volts is very excessive. The speed should not exceed 100 revs. per min. for continuous-current meters, and 40 or 50 revs. per min. for alternating-current meters. It would be an advantage if all makers could agree on one standard speed for alternating-current meters, the majority run at either 40 or 50 revs. per min. A speed of 40 revs. per min. is probably the more satisfactory. The pressure test for meters should be 1,000 volts (alternating) for meters up to 250 volts, and 2,000 volts for all meters above that pressure, and the pressure should be applied for one minute. Dr. Garrard's suggestion of 15 minutes is hardly required. For metering polyphase currents, meters should have at least two single-phase elements together on one meter. The so-called balanced-load meters having one element should be prohibited. The use of two or more separate single-phase meters, except in the case of three-phase 4-wire meters when the pressure is taken to the neutral, is not advisable, as at power factors under 0.5 one meter is reversed and it will not register equally correctly in either direction; further, it is likely to be a cause of trouble with consumers. The standard specification for current transformers requires careful handling; the phase angle, of course, should be kept as small as possible, say $\frac{1}{2}$ degree

between one-tenth and full load, but in the case of current transformers for high pressures such as 20,000 volts, this may have to be exceeded owing to the requirements of insulation, and of course safety in operation must always come first. Many authorities, however, do not allow metering on the high pressures.

Sufficient attention has not been given to the question of temperature coefficients of continuous-current meters, and this is probably of more importance than the 1/20th load accuracy of small meters. I am glad that this point was gone into by Mr. Fawcett at Birmingham. It should be quite allowable and is most necessary to test current and pressure transformers and meters separately. It is strongly advisable to test polyphase meters on a polyphase load and with the elements in the correct phase rotation. Tests at unity power factor and at a lagging power factor of 0.5 by means of a motor, and then with the direction of rotation of the phases (and of the motor) changed, together with another test at a lagging power factor of 0.5, give a good idea of the correctness of the balance of the elements and of their power-factor adjustment.

Mr. S. SIMPSON: It is noteworthy that this paper should come from one so closely connected with the meter section of the industry, for this specification should be one of the most important to the supply section in view of its very direct bearing on revenue. With regard to alternating-current meters, it is manifest, the more one considers this question, that revision on lines similar to those suggested by the author is desirable.

Clause 2.—I should like to ask, Why stop at 500 amperes? It is now very frequently necessary to go up to 1,000 amperes and even higher. Perhaps the author has in mind the use of current transformers above 500 amperes. On a medium-pressure circuit at what capacity would he draw the line between putting the current coil in the main circuit and adopting a current transformer with a standard secondary current of 5 amperes at full load? My own opinion is that for above, say, 100 amperes, the current-transformer combination is frequently the cheaper, often more convenient for connecting up, and incidentally simplifies stocking.

Clause 6.—I endorse the remarks by Mr. Roles regarding the desirability for standard marking of terminals and standard connections and as to the use of well-secured terminal lugs of ample size. I have not checked the sizes of the cable holes, but these should as a minimum be such as to accommodate rubber-covered cable based on the Institution rating corresponding to the full-load capacity of the meter. One frequently notices the same drilling for, say, a 5-ampere and a 50-ampere meter; the holes are all right for the former, but quite inadequate for the larger size. A provision for screwed-conduit wiring right up to the terminal cover and in metallic connection with the same is a feature to be commended to the careful consideration of meter manufacturers. Motors, switchgear, and fittings have already come into line in many cases as regards this point, but at present we stop short at the meter in a way which is frequently neither safe nor slightly and is certainly not an engineering finish to an installation.

For a supply authority a provision for stating the purchaser's particulars, such as "(Purchaser's) Meter No. . . . The property of (Purchaser's Name)," is extremely desir-

Mr.
Longman.

Mr.
Simpson.

able, either in the form of a separate label to be fixed subsequently on the front of the case, or as part of the maker's label, but not on terminal covers which, when frequently removed, are apt to be changed from meter to meter in the absence of any distinguishing mark.

The modification of the figures in Clauses 16 and 17 for the number of watts lost is also desirable. Many makers can offer this improvement, and, after all, the determination of this and similar factors in a specification rests largely on what the best achievements are.

Clause 27.—This is very important when dealing with industrial loads of indifferent power factor, and for polyphase circuits. Whether polyphase meters or single-phase meters are used, one element may be running at any power factor down to zero. This power-factor error I think should be graded, and it should be clear that at any rate in the case of single-phase meters the power factor is not necessarily that in the load circuit or the 3-phase power factor, but the cosine of the angle of lag or lead between the current in the series coil and the pressure applied to the shunt coil of the meter.

Regarding the use of polyphase meters for 3-wire circuits, my opinion is that a 2-single-phase-meter method offers the greater advantage, since a ready means of arriving at the average power factor of the load is obtainable from the ratio of the readings, and any serious error is soon detected and located to the faulty element. Moreover, there is very little difference in the first cost, at any rate not sufficient to outweigh these advantages, to which must be added simplified stocking. It will be desirable that, after this specification has been amended, the author's suggestion that meters sold as complying with it should be so marked, be adopted. I would, however, exclude all polyphase meters for balanced loads, which meters frequently lead to much trouble when indiscriminately used.

Mr. W. B. WOODHOUSE: The author's proposed addition to Clause 6 would be more valuable if he gave us the basis on which his recommendation as to the size of terminals is made. The size of the terminal holes should depend on the size of the cable required to carry the rated current and on the area of contact between the cable and the terminal block; that is to say, it is governed by the permissible current density in the cable and the permissible current density per square inch of surface contact. The holes must therefore be of a diameter sufficient to admit the proper cable, and on the basis of the Institution rating for rubber-covered cables the diameters of the holes recommended for all meters up to the 100-ampere size are sufficient, but for larger sizes this is not so; for example, a 250-ampere meter requires a $37/0\cdot112$ cable, but the hole recommended has a diameter of $0\cdot7$ in. and the cable a diameter of $0\cdot728$ in. A calculation of the surface available for contact between the

cable and the terminal shows that the current density varies from 32 amperes per sq. in. in the 10-ampere size to 95 amperes per sq. in. in the 100-ampere size. The smaller sizes therefore have holes which are too large; but this is probably on account of the design of the clamping screws. I consider that for meters larger than the 100-ampere size the type of terminal discussed is not satisfactory, and that it would be preferable to adopt terminable posts and cable lugs or some other method of making contact.

Mr. S. H. HOLDEN (*in reply*): I think Mr. Roles does not fully appreciate the dangers of non-magnetic cases for meters; an aluminium case can be squeezed with one hand so as to touch the armature. The case should always be very strong, for the "ingenious Chinaman" is not by any means confined to China. The faking of meters is carried to the point of a fine art in South America, where devices for making meters read low are actually advertised in the papers. I quite agree as to the importance of a uniform position and marking of the terminals, and I think that for polyphase meters in particular this is important. With regard to the suggested use of the word "kelvin" instead of "kilowatt-hour," the difficulty about adopting that term is that I wish to make the British Standard Specification one of world-wide application. "Kilowatt" is understood everywhere. As to the loss in the pressure circuit, my suggestion was based upon what I believe to be about the best standard practice at present. The specification should contain a provision limiting the character of the insulating materials used in meters. Limiting the maximum speed to 80 or 100 revs. per min. would be an advantage, and the manufacturers would soon fall into line with that suggestion. The abolition of the change-wheel in ampere-hour meters is rather a counsel of perfection, though manufacturers would be very glad to get rid of it. I do not wish to suggest that the manufacturers should always put holes in the meter cases for their customers' labels, but only that there should be a standard size of label and a standard position for it.

Mr. Longman's suggestion as to subdividing the specification for different classes of meters is a very good one. I would carry it even farther and have other sections for continuous-current watt-hour meters and for switchboard meters. My firm have supplied moulded glass covers, but do not find that there is much demand for them. The standard direction of rotation, the standard direction of current, and the standard arrangement of terminals on polyphase meters which have been suggested, are most important. I consider it very necessary that a limiting temperature coefficient should be mentioned in the British Standard Specification. A standard direction of rotation both for the armature and the counter hands is a useful suggestion. My suggested figures for the size of terminals should also be modified as indicated by Mr. Woodhouse.

INSTITUTION ANNOUNCEMENTS.

ANNUAL DINNER.

The Annual Dinner of the Institution will be held at the Hotel Cecil, Strand, London, on Thursday, 5th February, 1914, at 7.0 p.m. for 7.30 p.m. Applications for tickets should be made not later than Saturday, 31st January.

THE WIRELESS SOCIETY OF LONDON.

Members are invited to a meeting of the Wireless Society of London to be held in the Lecture Theatre of the Institution on Wednesday, 21st January, 1914, at 8 p.m., when Mr. A. A. Campbell Swinton will deliver an address on "Wireless Telegraphy" (experimentally illustrated). During the address special signals, audible to the meeting, will be received from the Eiffel Tower.

DISCUSSION ON

"BRITISH PRACTICE IN THE CONSTRUCTION OF HIGH-TENSION OVERHEAD TRANSMISSION LINES."*

BEFORE THE INSTITUTION, 8TH JANUARY, 1914.

Mr. W. B. WOODHOUSE: Since Mr. Addenbrooke read his paper in 1905† the question of altering the law in regard to overhead lines has been brought before the Institution on several occasions. I am quite in sympathy with Mr. Welbourn's recommendations, and I wish him success. The comparison of the cost of overhead and underground lines that is given on page 178 is very interesting, but the author does not make it clear whether he capitalizes the cost of wayleaves for the overhead line. That frequently amounts to something like £100 per mile, that is to say, the value of a strip of land 10 yards wide for the whole length of the line. If we had in this country what the majority of other civilized countries have, namely, powers of compulsory expropriation for the purpose of overhead lines, we could, by paying a reasonable price for the land, purchase it outright for a smaller capital outlay than we frequently pay for wayleaves, and we should have what is of vital importance to us—security of tenure. As to design, the formula that the author gives for calculating the pressure-drop is perfectly correct if it is assumed that the current distribution throughout the wires is uniform; but the formula is an awkward one to use. For the purpose of calculation it is much easier and sufficiently accurate for lines such as those which the author considers, to express the drop by $V_R \cos \phi + E \sin \phi$. This is correct to within a small percentage for such comparatively short lines and for lagging currents. The author avoids discussing tension in wires and the effect of elasticity in modifying the stresses due to temperature, snow loading, etc. I do not think a reference to elastic elongation at the moment of fracture is of any value in considering overhead wires, and I would therefore disagree with his suggested specification for aluminium wires. I think it is useless to measure elongation on a 5-in. specimen. The only important elastic elongation that we need consider is that within the working stresses, which the Board of Trade confines to much below the limit of proportionality.

The author seems rather to warn us against condemning offhand the use of aluminium wires. I do not think that is necessary nowadays; but I think we must take into consideration a point which he has not mentioned, namely, that greater sags and a wider spacing of wires are necessary. Therefore the whole supporting structure becomes higher, and heavier because it is wider, and the reactance of the line is increased, that is to say, the pressure regulation of the line is not so good. Taking the author's figures for a 0.15 sq. in. conductor, if aluminium is used the spacing is 20 per cent greater than for copper, and the pressure-drop is increased by about 4 per cent.

With regard to earth-wires, under the latest model conditions issued by the Board of Trade it is practically essential to consider the use of a continuous overhead earth-wire. I think such a wire is a valuable safeguard. A number of tests taken on earth-plates have shown that the resistance may vary between 5 ohms and 150 ohms. In the dry summer which we had two years ago I know of one case where a 10,000-volt line came down on the sun-baked earth and did not trip the circuit-breaker for an appreciable time. It is thus unwise to depend on a single earth-plate, and to couple a number of earth-plates together with a continuous earth-wire is sound practice. As to the value of the earth-wire as a protection against lightning, I have noticed that with a vertical formation of wires the arcing due to a lightning stroke being followed by the line current has taken place between the top two wires. It rather looks as if the top wires protect the bottom one; but I do not know whether that is really the case. I think I can fully agree with the author's conclusions in regard to lightning arresters. Lightning arresters remind me very much of boiler compositions. Both are an excellent protection so long as the conditions remain the same as those for which they were purchased. Unfortunately, however, the conditions change, and in the majority of cases the arresters are no use; certainly they will not protect any line against a direct lightning stroke.

* Paper by Mr. B. Welbourn (see p. 177, No. 226).

† *Journal I.E.E.*, vol. 34, p. 511, 1905.

Mr.
Woodhouse

In the case of a direct lightning stroke the trouble is usually quite local, and lightning arresters on another part of the system are of no great value. I do not quite follow the author's argument with regard to the spacing of wires. There is no regular law in the spacing that the author recommends, and I think the minimum spacing with voltages such as we are considering rather depends on the clearances necessary at the points of support. It is necessary to maintain a certain minimum clearance between the conductor and the insulator supports; that in most cases regulates the spacing of the wires, except in the case of very long spans. With long spans the swinging together of the wires must be taken into account; but if we adopt the author's basis, then if the length of the span is doubled the spacing is increased fourfold. Experience, I think, shows that to be unnecessary. The terminal arrangements are really the most important from the point of view of maintaining the supply. The cable dividing-box that the author has shown is very interesting. I should imagine, however, that it is rather difficult to make a good job on the top of a high pole in bad weather. All such boxes have to be filled and the joints made in position; so that it is important to have a box which is easily filled and repaired. I have found from experience that in the type of box having the insulator coming out of the top the insulation breaks down in course of time whatever the design may be. The compound shrinks, the box is heated and cooled every day, and moisture eventually gets in. I quite agree that the conductor should not come out of the top, and I think it advisable that inside the box no part of the conductor should be above the compound. I have tried a design of box which I think gets over the difficulties. The conductor is completely covered by compound; there is no fear of water trouble, and the clearance between the terminals is kept as great as possible. The small amount of clearance provided is a weakness of a large number of boxes, and it is the weakness of the box that Mr. Welbourn has shown us on the screen. The clearance between the conductor and the earthed metal is very small. Not only should the clearance be as large as possible, but it should also be possible to renew the insulators with the box in position with a minimum of trouble.

There is one other point. Fig. 20, which illustrates the method of leading-in bare conductors to the station, seems to me a direct incitement to birds to shut-down that line. I have tried that type of design, and the birds think it is specially designed for their convenience. It would be much better, I think, to bring the slate panel flush with the outer surface of the wall, or to tilt it up so that its forward face is downwards. In conclusion, I should like to say that I think the paper is such an excellent summary of present-day practice and of the points that have to be considered in carrying out this kind of work that it will become the transmission-line engineer's *rade mecum*.

Mr. A. P. TROTTER: The ideal of Board of Trade regulations is that they should be a record of the best practice of the day. As practice varies, the regulations should follow. They are perfectly familiar to those engineers who have to deal with overhead construction, and the only complaint made about them by others who are not familiar with such work is that they are too short. Some

engineers would like about 25 pages and a roll of blue prints. There are a few purely technical points I should like to touch upon. On page 185 the author observes that the minimum size of wire for high-tension lines is No. 14 S.W.G. I would say that is also the minimum size that should be adopted for low-pressure wires. It represents a wire of 200 lb. per mile—a gauge always in stock. On page 187 there are two references to insulators which I think are rather contradictory. In the first column on page 187 the author says that the glaze may break and cause the insulators to fail, and at the bottom of the same page he says they must be vitrified throughout. It is of vital importance that the insulation shall not depend upon the glaze. It is important to bind the wire on so tight and so well that it shall not rub the glaze away. A wire working upon the insulator having rubbed off the glaze, the insulator acts as a grindstone and begins to cut the wire through. But quite apart from that it is very desirable that the insulation should be thoroughly vitrified. In that connection I think that the specification for an insulator at the end of the paper is insufficient. I think something should be stated about the nature of the insulation when the glaze has been removed, so as to ensure that it is impossible for moisture to be absorbed. On page 188 the author refers to earth-plates, and I am very glad that at last a statement has been made in print of what an earth-plate should be. Some experiments were made upon the resistance of the earth-plates at my suggestion by one of the firms of contractors who, like so many contractors, are only too reticent in publishing the results of the valuable experiments which they make. I had heard of an earth-plate 5 ft. \times 3 ft. which had been specified by an engineer and which seemed to me to be a little bit large. I wondered what the difference between that and an earth-plate a foot square would be, and also between plates of various intermediate sizes. The experiments were made. Plates of various sizes were buried in the ground some 20 ft. apart, and during various kinds of weather current was passed between them, the drop in pressure taken, and tests made. It was found, as the author states, that a plate of about 1½ ft. square is approximately the best size. If a larger size than that is used, very little is gained in most soils; whilst in the case of smaller plates the resistance begins to increase. A plate about 18 in. square and ½ in. thick allows a good bond to be made; and if the plate is specially cast, so much the better. Some engineers go to the "scrap-heap" for plates of about the same superficial area. At the top of the next column on page 188 the author mentions wires coiled up at the base of a pole. That is done by telegraph engineers. It is perfectly obvious that such a coil of wire is of no good whatever for a 10,000-volt line—or as a matter of fact for a 400-volt line. I am glad to see that the author suggests that the earth-wires should be covered in.

On page 192 the author remarks: "Considering these facts, it would seem that the time is approaching when it will be justifiable to ask for the Board of Trade's consent to run high-tension lines along public roads." The time has come; the time has passed some time ago. I have proposed it myself to more than one engineer. That is to say, when I began to be quite familiar with the Merz-Hunter gear I saw that if it could be depended upon to work—and it seems that it will—there was no difficulty in running

Mr.
Trotter

10,000 or 20,000-volt wires along the country roads. I have asked engineers whether they would like to do it; but on speaking to those who are engaged in setting out these lines rather than in constructing them, it will be found that they say it is hardly worth doing, simply because any road that is straight enough to be worth while going along is used already by the Post Office; whilst other roads are too winding to be worth troubling about. At the same time where wayleaves—which are a most serious matter—are difficult to obtain, it is quite worth while to threaten the owner that it is intended to go along the road. But there is one thing that I should like to mention about the Merz-Hunter, the Merz-Price, or any other gear. The gear depends, as is well known, upon a small armature that can be attracted. If that works freely and does its work it is all right; but those who have had experience of working with automatic gear know that sometimes if the gear is set fine enough to do the work intended it operates too often. If these gears operate every time that a bird pecks at an insulator or a bit of wet straw blows across the line, and also exhibit nervous tendencies and cause trouble, the obvious thing would be to tie them up with a bit of string.

On page 103 the author speaks of overhead transformers on poles, and he showed a photograph of one of them. I know that transformer, I know of one other, but I do not know of a third. The regulations have been made, but I am bound to say that I do not like this practice. A Japanese engineer called on me some time ago and asked me to show him our protective and safety devices. I wanted to know what he wished to see them for. He replied that there was a law in Japan to have one in every house. I said "Why?" He said the high pressure got on to the low through the transformer. I asked him how that came about as we never had such trouble in this country, and he explained that every transformer in Japan is on a pole outside the house and is a frequent cause of fatal accidents. The transformer illustrated is properly earthed and no doubt is safe, but I should be sorry to see small transformers the size of a hat-box dotted along outside every farmhouse on a 10,000-volt line. Then there is one very small point about the specification for masts to which I should like to refer. The author says that the bottom part is swung up and erected and the joints made. I think the very well-known usage in mechanical engineering should be followed, to have the bolts in shear and not in longitudinal pull. I have seen towers erected and fastened with holding-down bolts, but I do not think that is sound practice.

Commander O. SCHWANN, R.N.: There is one point which I think has not been brought out in the paper, namely, the effect of overhead high-tension wires on aerial navigation. Of course, at the present time aerial navigation can scarcely expect to make very many demands, because it is in its infancy. But I think everybody will agree that aerial navigation is bound to increase, and it seems to me that we might usefully consider a few ways in which overhead wires affect aerial navigation. When the time comes for aeroplanes and airships to be used commercially, they will perhaps be able to demand what they need in this respect. All kinds of overhead wires, both telegraph lines and also high-tension wires, affect the navigation of air craft very greatly. High-tension wires have a particular effect for two reasons; first, the liability of such

wires to cause a lighter-than-air craft, *i.e.* an airship or balloon, to catch fire on coming in contact with them; and secondly, the fact that high-tension wires are erected as far as possible in open country clear of roads and towns. As regards setting fire to air craft, this only applies to airships. If an aeroplane strikes an overhead wire it does not very much matter whether it is a high-tension wire or a low-tension wire, because there is sure to be an accident; but high-tension wires are, I think, a distinct danger to airships which happen to trail against them. An airship or a balloon frequently carries a tail rope dragging on or near the ground and suspended from the airship. If that rope earths the high-tension wires, of course it may probably cause trouble to the electrical circuit, but I am not quite sure that it will not also set fire to the airship. The airship has a very large capacity, but I do not know whether the fact of the rope's making contact between the high-tension wires and the airship will not immediately cause a spark which might ignite the hydrogen. The second and more practical case is that all high-tension wires are erected as far as possible in the open country. A navigating air craft expects to be troubled near a town, and it cannot expect to be able to land with safety anywhere in urban districts. But in the open country and across moors where there are no roads, it hopes to be able to effect a landing without striking a wire which at present it finds very difficult to locate. That is the great trouble with high-tension wires, which I believe is chiefly experienced upon moors. The only point that seems to affect the matter at present is the difficulty of finding out where these wires have been erected. I understand it is not very possible to obtain complete charts showing where all such lines are. It is proposed to make aerial charts of England which will indicate the most dangerous lines, so that an airship passing over open country will notice by a red line that it is not such a safe place on which to land as it might be thought from the aspect of the ground. Lines running along roads are of course not so dangerous, as a road is easily seen, and one always expects to find wires there. It seems to me that it cannot be very long before a serious attempt will have to be made to try and let the Aerial Departments have some method of learning where every wire is erected across country, other than along roads or within a certain radius of towns. A great difficulty to which I wish to draw attention is that of seeing the wires. Telegraph wires are very noticeable from the ground, but they are particularly difficult to see from the air. Of course from the aerial point of view one would like to have them made more distinctive, and I suppose that would cause some inconvenience to people living near them. I think that by having them, say, more brightly coloured, or something of that sort, we should be greatly assisted. We are, perhaps, a long way from getting what we suggest, but I merely wish to point out these facts so that they may be taken into consideration.

Mr. C. W. KAY: I should like to describe a new design of steel pole which Callender's Cable & Construction Company have been developing during the past two years. (Mr. Kay proceeded to show a series of slides descriptive of this pole.) It will be seen that the structure consists of five tubes, one vertical tube resting on four inclined tubes, and all five tubes meeting at a point, the complete pole being braced together by wire stays. The

Commander
O. Schwann.

Mr. Kay.

Mr. Kay.

design is exceedingly simple and offers a great many advantages over ordinary lattice-work poles, especially as regards shipping and transport for foreign orders and as regards erection anywhere. In the case of such a pole which was tested to destruction, the conductor wires were still well off the ground, and the supply would not have been interrupted. The upper member does not entirely fall to the ground until the deflection becomes so great that the wire stay passes the point where all the tubes run together. In the simplest type of pole where the stays run together at the top, the vertical tube is made thicker in order to carry the bending stress due to the load on the wires. In another design the stays are divided into pairs, and the points where each pair of stays is attached to the upper framework are some little distance apart, the effect being that the vertical member itself is braced and consequently has not to be made thicker as in the previous example. Moreover, the provision of a smaller diameter tube above the cross-arm gives a good shoulder to carry the cross-arm and the pull of the stays. A pole of this type was also tested to destruction. The interesting point is that, contrary to expectation, the pole failed by the vertical member bulging in the direction of the load. Most poles fail by bending in the contrary sense. We tried to find an intermediate position to which to attach the stays, and which would give us neither one effect nor the other. We were largely successful in this. The main wire stays were attached to a different point on the cross-arm from the point where the short upper stays were fastened, in order to brace the cross-arm to the upper part of the vertical tube. A pole of this type was also tested to destruction and, weight for weight, it carried considerably greater loads than either of the previous types. All these poles were designed to fail at four times their working loads, and none of them failed at smaller loads than was anticipated. (Mr. Kay proceeded to show some slides illustrating poles actually erected in the Newcastle district for the Newcastle-upon-Tyne Electric Supply Company, these poles varying from 61 to 65 ft. in height and carrying six wires. Further views were also shown of some poles now in course of erection in South Wales, including several views of poles at the end of a 1,420 ft. span. A noticeable point with reference to these long-span poles was that, contrary to general practice, no substantial modification was necessary in the design in order to carry the extra loads. Another view showed a pole erected at Sheffield, the height of the pole being 81 ft. above the ground.) I think it must be evident to everybody that the maintenance and up-keep of a pole of this design is considerably less than that of an ordinary lattice structure. Painting is a comparatively simple matter, and there are no awkward corners or pockets where water can lodge, and only one side of the material is exposed to the weather. Moreover, the foundation of each of the lower legs consists of a large square plate. One plate out of four at each pole is galvanized and forms a very effective earth-plate.

(Communicated): Mr. Welbourn has asked me what precautions we take to avoid corrosion of our poles, and has suggested that steel poles are unsuitable in the neighbourhood of large towns or in manufacturing centres. Dealing first with the question of corrosion, this might take place on the tubes composing the structure either

below ground, due to moisture or impurities in the soil, Mr. K. or above ground due to the action of the weather and impurities in the air. The tubes we are now using are made of high-tensile steel having an ultimate strength of nearly 40 tons per square inch. This steel is far less liable to corrosion than ordinary mild steel or wrought iron, and it is in some respects even superior to cast iron. The closeness of the grain as well as the hardness and uniformity of the material are factors which greatly tend to reduce corrosive action. A large amount of what is usually called "corrosive action" is really galvanic action, and this is naturally less pronounced in a homogeneous material, such as high-tensile steel, than it is in the lower grades. Furthermore, only one side of the material is exposed to the weather, so that, when compared with the lattice towers, these poles enjoy a distinct advantage in this respect. Where the lower ends of the tubes enter the ground they are usually wrapped with a canvas lapping which is thoroughly impregnated with a good bitumen preservative; the insides of the tubes are also well coated with a bitumen preservative. Another point to be borne in mind is that in designing a pole we calculate the diameter and thickness of the tube in order to give it the necessary resistance to buckling. A strut of uniform thickness throughout its length may of course taper towards its extremities, and this is another way of saying that corrosion even if it does take place is only of importance at or near the middle of each tube, and that the tubes may waste away at the ends until their section is reduced to 25 per cent or less of the original area. With regard to corrosion of the wire stays, this is not a serious matter if good material is used. The stays are of course galvanized, and we usually supply them with a factor of safety at least double what is asked for by the Board of Trade. Here again if corrosion does take place it will be a long time before the factor of safety on the complete pole is even slightly reduced. I might also state that there is certainly no reason to anticipate a greater corrosive action on these poles than usually occurs in connection with ordinary wood poles, which are of course dependent on ironwork to a very large extent. It is well understood that in the neighbourhood of manufacturing centres more care must be given to painting, and the expenditure on maintenance must necessarily be higher than on similar work erected in pure country air. The fact remains, however, that nearly all structural ironwork, whether bridges, roofs, machinery, or anything else, is as a matter of fact erected in or near towns and manufacturing centres, and that the upkeep of such ironwork is not a serious matter; nor is the life of steelwork unduly short.

Mr. C. VERNIER: I think that this paper is very timely, as although several papers on long-distance transmission in other countries have been presented to the Institution, I believe this is the first time that we have had a paper on overhead lines erected to meet British conditions. It must, I think, come as a revelation to many here to-night to learn that there are something like 1,000 miles of high- and extra-high-tension overhead lines in the United Kingdom, most of which have been erected during the past five years. There are, moreover, 115 miles of lines in operation at a pressure of 20,000 volts. The author says: "It may be taken for granted that pole lines have come to stay." I think the table he has given on page 178

illustrates very clearly why this is so. I only wish he had extended it to both higher and lower voltages, for if he had taken 3,000 volts he could not have made out a very strong case for overhead lines, especially if he had compared them with underground cables designed more in accordance with the work that they have to do than with our engineering standards. An ordinary 3,000-volt cable will withstand a pressure of between 40,000 and 50,000 volts without breakdown, a fact which shows that there is room for a saving in first cost, although this is even more apparent at somewhat higher voltages. At the other end of the table, if the author had taken 40,000-volt lines and cables, the capital cost of the overhead line would only have been about one-third of that of the underground cables. It is not often realized that the cost of an overhead line does not depend within these limits of pressure to any great extent upon the voltage. This is quite clearly shown in the table, where the cost of a 6,000-volt line is given at £900 per mile and that of the 20,000-volt line at £950, the difference being entirely due to the difference in the cost of the insulators. Apart from these the cost of the line depends upon mechanical considerations, and it is merely a question of supporting a certain size of conductor to meet certain wind pressures and of complying with similar factors of safety. Moreover, the lower the voltage the heavier is the conductor usually employed, and the heavier the construction required; in these respects it is therefore rather to the disadvantage of the lower pressures as compared with the higher. A previous speaker mentioned that the cost of the wayleaves was not included in the table. That is quite true, and I think he mentioned a figure of £100 per mile as the capitalized cost of these wayleaves. I am of opinion that this is perhaps on the low side and will of course vary according to the district, but it must not be forgotten that a great advantage of overhead lines is the fact that they enable "short cuts" to be taken across country. If underground cables be taken by similar "short cuts," wayleaves must also be paid for, while if they are taken along roads without wayleave charges this will add possibly 30 to 50 per cent to the route length, so that the cost of wayleaves is not perhaps so important as it might appear without these considerations. The author has quoted several extracts from an address which I gave recently,² and he has mentioned the difficulty of negotiating wayleaves. This becomes a serious difficulty in some cases because the landowners are able to dictate their own terms. Such a one may be shooting in India for six months, and delay must often occur until he comes back before any progress can be made. If the particular piece of land happens to be in the middle of a long line it is very awkward, and cases have occurred where long lengths of route have had to be diverted. I think it would be an excellent thing if the Institution would consider this matter, although I fear that at the present time there is not very much hope of success; for our ideas of the rights of landowners have been handed down to us from feudal times, and nothing short of a revolution therein will enable progress to be made in the way suggested.

The second point Mr. Welbourn makes, namely, the curtailment of the absolute veto that the local authorities possess, is one where I think we could make out a good

case. I think the clause in the Electric Lighting Acts bearing on this matter arose, if I am not mistaken, from the practice which originated in London of running high-tension wires over house property in the early days of electricity supply. I think it was felt that the local authority should have the absolute right to determine whether it would allow overhead wires of any kind within its district, not only over house property, but also over or along roads and streets. Curiously enough, however, this power was only made to apply to statutory undertakers. I do not see very much objection to the clauses in the case of an undertaking working under a provisional order. If the local authority choose to veto overhead wires in its district, the public whom they represent have to pay for it in the end, as Dr. Ferranti recently remarked. But when we come to consider long trunk lines which may pass through a number of local authorities' districts one single authority should not have the power to jeopardize the success of a scheme. Further, it is not always possible for a company's relations with the local authority to be harmonious, and the absence of any right of appeal in these circumstances may lead to victimization.

With regard to factors of safety I entirely agree with the author. I have no wish to see any reduction of the factors of safety now allowed by the Board of Trade on the work with which I am connected. The snow-laden wires that the author showed on the screen illustrated an experience that the Newcastle-upon-Tyne Electric Supply Company went through last January. I think it caused considerable surprise. I doubt very much whether many people had any idea that such severe weather conditions were possible in this country, even although those referred to were exceptional. The Newcastle lines weathered the storm, but I think the author gave rather a false impression of what happened. Only four out of 42 lines were affected, and only one very badly so. This was a line carrying a most important supply, and the engineer-in-charge repeatedly switched the line in under practically short-circuit conditions in an endeavour to maintain supply, with the result that the conductors were fused in numerous places. The other lines referred to only suffered to the extent of having a number of insulator pins bent and channels twisted because of uneven snow loading on adjacent spans. One important thing noticed was that the heavier conductors, 0·1 and 0·15 sq. in., did not collect snow, and that no trouble whatever was experienced on such lines. As a result we have since been installing on important lines heavier conductors than are really necessary to deal with the loads, so as to obtain the greater margin of safety. On the question of double-circuit lines, I think that if a duplicate supply be necessary, it should not be provided by making use of a second circuit on the same poles, or even along the same route. The above was the only interruption of supply we experienced during the storm, and in this case the duplicate line was on the same poles pending completion of a ring main. Duplicate supplies should for this reason be given as far as possible by different routes, as in all storms there are areas and certain directions of the lines relative to the storm where the effect is more severely felt, and it is often possible by means of a ring main to maintain the supply over one line when the other is affected. It will be of interest to record that not a single pole was damaged or broken in this storm, and

* *Journal I.E.E.*, vol. 52, No. 223, p. 17.

overhead transmission systems in Norway in which the maximum pole spacing was 1,970 ft., upon which span an aluminium-copper alloy was successfully employed. Some transmission systems were at present operating at 110,000 volts, and others were now being built for 150,000 volts. Some of these systems showed a greater aggregate length than the total transmission at present in operation in England.)

With regard to jointing, I note that the author advocates butt-welded aluminium connections. This is a satisfactory type of joint where it is not placed under stress, but it obviously has only the tensile strength of annealed aluminium, which is some 50 per cent less than that of the hard-drawn wire. As far as my experience goes, I have always found the torsion-sleeve type of joint to be most satisfactory for use in the run of the line, and it is both mechanically and electrically efficient. I am very glad to note that the author has carried out some practical tests on the elastic limit of aluminium wire, because it is an important point and should be borne in mind when the design of the line is under consideration. I should like to point out that his tests were taken on wire, whereas aluminium is recommended only in the form of a stranded conductor, in which form the elasticity of the material will be much greater. I trust that on some future occasion the author will give us the benefit of his experience of stranded conductors in this respect.

MR. W. M. MORDEY: May I ask Mr. Jacob one question? He says that aluminium wires do not collect ice or snow, whereas copper wires do under the same conditions. This seems a very extraordinary thing. I should like to ask Mr. Jacob whether he can speak on that point from his own experience.

MR. JACOB: The statement is taken from the current issue of the *Electrical Review*, and was originally made, I believe, by Dr. Marguerre, the expert who constructed this hydro-electric power system. He has had the advantage of carefully watching these lines for some years.

MR. J. S. HIGHFIELD: In regard to insulators, I find from experience that it is most important there should be if possible no moving part between the porcelain and the wire, so that it is impossible for the wire to move with respect to the porcelain. As Mr. Trotter has said, the glaze wears off, and then the wire gets worn through. With the suspension type of insulator considerable care must be exercised to see that the moving parts, which are essential in that type of insulator, are of ample size, so that they will not wear through quickly. With regard to earth-plates, it is much better to use two small earth plates than one large one. There is no reason at all for installing a very large single plate. If several small plates are used they should be between 4 ft. and 8 ft. apart to get the best results.

MR. J. C. WIGHAM (*communicated*): The following notes on the overhead work in Cornwall—erected to the designs and under the supervision of Mr. L. A. Hards—may be of interest. There is only about one mile of underground high-tension cable in the county, that entering Penzance. There are 39½ miles of overhead lines, 12½ miles on pin insulators, and 27 miles with suspension insulators. Underground cables would have been impossible, owing to their being too expensive and to the fact that there are no direct roads for several routes. The first lines erected were on

wooden "H" poles, 240 ft. span, double circuit (6-wire), M^h copper. The next lines were on steel poles, partly tubular flexible and partly lattice, 400 ft. span, double circuit (6-wire), copper. Latterly some aluminium lines on wood poles, 120 ft. span, have been used. Double-circuit overhead lines are substantially cheaper than 2 single-circuit lines. Aluminium wires on wood poles at short spans are the cheapest construction; but in many cases wayleaves would make such construction impossible. Copper wires on steel poles at 400 ft. spans come out cheaper than on wood poles at 240 ft. spans, and make wayleaves extremely simple; with 400 ft. spans it is possible to place the poles in the hedges uninterrupted for many miles. To carry aluminium wires on 400 ft. spans means for, say, 0.1 sq. in. copper equivalent, 50 per cent extra windage and approximately 50 per cent extra sag, and the towers must be 6 ft. higher and 50 per cent stronger laterally. As the cost of towers varies approximately as the square of the height, any saving in the cost of conductors is lost in the extra cost of towers.

The pressure of supply is 10,000 volts, but practically all the lines would carry a pressure of 20,000 volts. The only trouble has been with a faulty design of link-type suspension insulator. The Callender clip has been used on pin insulators and has so far proved entirely satisfactory. The storms in Cornwall are the severest in these islands; 90-miles-per-hour gales have been recorded since the lines were erected and have caused no damage. Trouble from birds has been experienced on the pin-insulator lines, notwithstanding the fact that the neutral of the system is earthed through a very high resistance—so high that it is possible to run with one phase earthed. Apparently two birds must have earthed different phases at the same moment.

In regard to wayleaves, the landowners and tenants have, with but few exceptions, been most reasonable. The railway companies and the Post Office have acted as if with the object of facilitating the power company's work, while insisting on their requirements for adequate protection of their telegraph and telephone lines. The Post Office officials especially have gone out of their way to work in with the power company's construction. It is needless to add that the action of the Board of Trade has been throughout to assist and not to retard development. At the same time it is absurd—particularly in Cornwall—that there should be any difference in the legal position of rural and urban local authorities, since there are as important towns in the rural areas as in the urban areas. Because fairly satisfactory wayleaves have been secured, the Cornwall engineers appreciate the highly unsatisfactory conditions under which other power companies have to accept wayleaves, and would heartily support any steps to improve the legal position in relation thereto.

The painting of steelwork is highly important in a salt-laden atmosphere like that of Cornwall. Dixon's graphite has up to the present proved superior to all the kinds of so-called bitumen paints that have been tried. So far the cost of painting has not proved excessive. Telephone circuits are only run on one line; bare copper on rolling insulators. The speaking on this line is not, however, good when there is an "earth" on this portion of the system. The line, which is in sections, is made fast

Mr. Wiglam.
Mr. Paton

at one end, but at the other is attached to a counterweight, which keeps the tension on the line uniform.

Mr. G. K. PARON (*communicated*): This paper comes at an opportune time, and it is to be hoped that the Council of the Institution will support Mr. Welbourn and do something to facilitate the use of overhead lines in this country. In the North Wales Electric Power and Traction Company's system we have scarcely any extra-high-tension insulated cable, the switchboard connections in the power station and all sub-stations being bare, supported on porcelain insulators. Transmission throughout is by overhead conductors, and I may safely say that by no other system is expansion possible. Where consumers are few and spread over a large area the cost of connecting lines must be cut down to a minimum, compatible with sound design and workmanship. Granted that the Merz-Price and Merz-Hunter systems are sound, yet the cost is prohibitive except in large systems where the selling area is compact and the demand large. In circumstances similar to those above referred to, the price per mile of overhead line given by the author might be considerably reduced upon a specification confined to actual essentials, and the comparison with cables would be more in favour of overhead lines. In negotiating power contracts, time is invariably of the essence of the contract, and it is not always possible in these circumstances to elaborate a route plan similar to Fig. 1, especially where the overhead line is of any length. Owners and tenants have to be dealt with, and they may be numerous. When another language enters into the question, as in North Wales, it is an added difficulty to surmount. There is nothing for it but patience and the tactful pursuit and removal of all the real and imaginary objections put forward. Even then one meets with "impossible" folk, and must be prepared to have the route blocked, compelling changes more than once, with consequent delay and loss to all parties—to the owners and tenants due to the driving way of a beneficent enterprise with its uses and amenities, and to the power company and its customers, actual and potential. Thus it is that wayleaves are often the stumbling-block to many useful schemes. Electric power supply companies are *par excellence* public utility companies operating under Acts of Parliament designed as much to serve and safeguard the public interest as to enable the company to earn a reasonable dividend on the necessary investment of capital. Where the public benefit is to be served it should not be left in the unchecked power of individuals to cripple the enterprise by unreasonable demands for wayleave rents or other conditions. The appeal urged by Mr. Welbourn against an unreasonable refusal of consent by a local authority should be widened to include an appeal to the appropriate Government department against unreasonable demands or restrictions sought to be imposed by owners and tenants. If the initiation of such an appeal required the support of actual or potential consumers as well as the power company, with the costs of the application charged to the power company, there would be ample protection against any idle invoking of Government aid.

Insulators and binders.—I must disagree with the author on the question of the flexible binder shown in Fig. 8. The "pigeon" or chafer will not prevent abrasion of the insulator, although it may protect the line wire. I have

seen many cases where the soft-copper binder has left its mark on the glaze of the insulator; and the chafer to be effective must be non-metallic. For this reason I adopted leather or pig-skin, and either of these meet the case satisfactorily. I would also remark that in the case of the flexible binder 4 or 6 strands of soft binding wire round the neck of the insulator take the strain due to wind pressure where the line wire is on the lee side of the insulator. In the case of long spans where the sag and consequent movement of the line wire on the insulator is considerable, these strands are all bound to stretch in time, and unless the binder is tightened up occasionally chafing will take place. The swinging of the line wire is also an additional reason for having a cushion on the insulator, and I believe this cushion should be between the line wire and the insulator—not between the insulator and the pin. On the only line on which we have insulators screwed on the pins with oiled hemp twine, I have frequently seen insulators rocking on the pin with the movement of the line wire. In any case it is sound practice to cement the insulators at corner poles and terminals, if not on the ordinary line poles, where it may be an advantage to replace an insulator without removing the pin. The binder shown in Fig. 9 suffers, in my opinion, from similar defects to that shown in Fig. 8, and I should think the strands of soft wire round the insulator must sooner or later stretch owing to the swing and vibration of the line wire. For heavy aluminium or copper lines I should prefer to see the line taken over the top groove resting on a leather chafer and then anchored to the insulator on each side by means of a clamp. This would permit ample freedom for the line to swing. The ideal binder should, of course, tie the line wire to the top groove, and the standard design of insulators with comparatively flat upper petticoat is not at all suitable for a side binder, as shown in the illustrations, now that long spans are being used. The author has not given us any information in regard to cement for insulator pins. It would be advantageous to have the experience of other engineers. Preferably the cementing should be done by the insulator manufacturers, as the facilities for doing it in works are much better than on site. As to the earth wire, this should be run overhead if possible, and is much more likely to be of service there than under the line conductors. We have a recorded experience where the overhead earth conductor was actually discharging to the earth-plate two spans distant, the brush discharge effect being actually seen by a visitor. Our experience of the Mosicki condensers is satisfactory so far, and we have not found the cost more than the quoted price for electrolytic condensers. In a mountainous district like North Wales, where our lines are nearly 2,000 ft. above sea-level at some points, it is essential to have protection of some sort. We had a brilliant display of lightning this Christmas, accompanied by heavy hailstorms. Probably we may get more lightning in this district than in other parts of the country. During 1913, vivid lightning occurred on 20 days as recorded by Mr. A. Lockwood, Station Superintendent at the Cym Dyli power station of the North Wales Power Company.

With reference to running telephone lines on the same poles as the power wires, I agree with the author that copper is preferable to phosphor bronze, our experience of the latter not being very satisfactory. In fact, we have had one case where owing to breakage the wire curled up

round the power wires. Undoubtedly a cable system is more secure, but the telephone system is intended primarily for communication to the station, in the event of breakdowns, from any point in the system, and with bare wires this is easily done in conjunction with portable telephones. By these means I have known occasions when the linesman located a fault and replaced a defective insulator in 10 minutes. In practice, rotating the telephone wires and transposing the line wires twice in each section or arrangement of power wires gives the best results. It is extremely unlikely that power conductors should fall, and the result would be serious in either case. Telephone fuses may be replaced quickly and are quite satisfactory in use. It is not good practice to run the telephone wires on spans over 40 yards horizontally as shown in Fig. 14. The wires should be run in vertical formation and "made off" at each transposition to give satisfactory results; but I am of opinion that the power wires should be transposed also.

Guarding of conductors.—The examples of road guards given by the author are all designed to earth the line wire in the event of the latter falling. The only reasonable place for the line wire to fall would be at the insulator, where it might fuse should the insulator break. A second insulator with anchor wire and clamp as designed by Señor Semenza should be quite sufficient to prevent the line wire from falling. Road crossings on this principle have been used in North Wales with the approval of the Board of Trade, although flat cradles have been erected under the wires as an extra precaution.

Mr. J. NELSON (*communicated*): There are several points in this paper which it seems to me require explanation and enlarging upon. In the first place, I do not think the majority of engineers fully realize the great saving in erection costs which can be made by spending a little extra time and care in fully setting out and organizing an overhead scheme before the actual work of erection is begun. It is ruinous financially if gaps have to be left in the line through wayleaves not being settled. The plan shown on page 178 is excellent, but I am sorry to say organization of this kind is the exception and not the rule. I am sure that all who have to do with the erection of lines will agree with me that a far better job can be made of a line when all details are settled beforehand, so that the work can be commenced at one or more points and carried out unceasingly to completion. It is surprising how much money can be saved by keeping up the enthusiasm of engineers and workmen when the work proceeds without hindrance. Factors of safety might also form the subject of a paper. A good many engineers who have not overhead lines on their system seem to look upon the Board of Trade as a bogey; whereas actually that department is always willing to consider special cases. It is quite obvious that any rules framed by a Government department must err on the side of safety for the public, but I think that each overhead line should be judged on its merits. In some districts the Board of Trade regulations are not by any means too high; whereas in others they are much too stringent. I hope eventually to see rules framed which will enable a supply to be given to many villages and farms adjacent to power lines. On page 180 we are given the breaking strain for stays. In connection with stays mention may be made of their various uses: Primarily the object of a stay is to take the extra strain due to the

change of direction of a line or the strain due to the termination of the wires. I do not think it is usually realized how important a factor stays are in preventing the line wires swinging together in a high wind. I have watched single-circuit lines erected on single poles under high cross winds, and have noticed the oscillation set up by the difference in the natural swing of the wires and the poles. A certain bad case of the line wires blowing together was cured by fixing stays at the terminal pole and at intervals on the line in such a manner as to keep the pole supports rigid, so that any swing on the line wire due to the wind was not made worse by the difference in swing of the poles themselves.

Galvanizing.—Even when the threads of stay rods or turn-buckles are galvanized and brushed it is just as well to paint them with a tallow and tar mixture so as to make subsequent adjustments easy. In districts where the atmosphere is corrosive all galvanizing should be painted with a preservative compound before the line is put into commission, otherwise the cost of maintenance and renewals will become very high in a few years.

Telephone line.—Fig. 14 shows a very neat arrangement but one which does not seem to be very satisfactory for districts where there is likely to be an accumulation of dirt on the insulators, owing to the small leakage path between the two wires. Possibly the illustration is only intended to be diagrammatic, and if so, it would be advisable in practice to increase the leakage path. A better arrangement is to use double J-bolts and insulators and terminate the wire off each side.

Wood and steel poles.—The author states that there has not been much experience in England of the Rüping process. I understand that on the Continent it has proved very successful—in practice creosote does drain from a Rüpingized pole and renders the ground antiseptic, although the quantity is not so great as with a Bethell pole. With the Bethell process a good deal of creosote is lost before the pole reaches the site of erection; this creosote might just as well be saved at the maker's works.

Guarding.—It is rather difficult to understand why the Post Office allow lines working at pressures below 3,000 volts to cross their wires and forbid lines carrying higher pressures; if the guarding arrangements are adequate, the higher voltage lines could safely be taken across the Post Office wires. High-tension wires have to be kept at least a pole and a half away from the Post Office wires where they run parallel with the latter; whereas low-tension wires are allowed to run parallel with them and as near as 6 ft. Surely the high-tension wires could be carried as near the low-tension wires if suitable guarding were provided. It is reasonable to assume that the inductive effect would be greater on a low-tension line carrying heavy currents than on an extra-high-tension line carrying relatively small currents.

Sundry details.—Where poles are planted on public land, I would propose that the number plates be placed higher than 5 ft. to avoid risk of malicious damage. The trouble due to climbing irons being used is one which can be greatly reduced if the linesmen are made to take short steps in coming down the pole; when long steps are taken it is difficult to get the spur out without tearing the wood. In conclusion, I think the author is to be congratulated

Mr. Nelson. on having compiled so much useful information in the Appendixes.

Mr. S. B. DONKIN (*communicated*): The prices per mile for an overhead line at different voltages appear to be higher than those generally obtainable if the cost of wayleaves is omitted. £550 to £600 per mile for a single line of equal capacity to that of the cable would appear to be a more reasonable figure (not including wayleaves). On page 179, under "Mechanical Design Formulae, Etc.," heading 1, paragraph 3, subheading (b) and beyond, the word "stress" is used when bending moment would appear to be the correct expression. Again, the formula given under (b) expresses the maximum bending moment at the ground line and not at 1 ft. from the ground line: the formula is correct if the words "at 1 ft." are omitted. The same correction should be made in subheading (c), and it would be more correct to give the result in both cases in "foot-cwt." instead of cwt. The total effect on the pole is called the "total 1-ft. breaking stress," but the author obviously means that the total bending moment at the ground line is the sum of (b) and (c). This total should be multiplied by the factor of safety (10), and then gives a value in bending moment which can be found in Table XX of the Post Office Technical Instructions XIII (after dividing the Post Offices values by D, as instructed); and opposite this figure the table gives the diameter of the pole required. Under the headings II, III, and IV, on pages 179 and 180, the word "stress" is used where tension or pull or load is meant. Under heading IV the factor of safety to be used for dividing the total maximum breaking load of all the wires is 5, and not that "to which they are stressed." Heading V would be more useful if altered to "Strength of Insulator Pins"; and a more useful form of equation, using the same notation is—

$$D^3 = \frac{\text{max. pull (lb.) by wire} \times \text{length of pin (in.) from channel to centre of wire}}{\text{breaking strength of mild steel in lb. per sq. in. (say 60,000)}} \times \text{factor of safety}$$

The author says a factor of safety of 4 should be allowed for pins, but he does not say on what loading the strength of the pin is to be calculated. I suggest that the pin should have a factor of safety of 2 when the line wire breaks on one side of it and the unbroken span pulls on it under the worst conditions. This means that the pin would be just strained up to or beyond its elastic limit and would give slightly to relieve itself of the strain. Under heading VII, on page 180, the column headed "Evenly Distributed Load in Tons" in the table is difficult to understand; but it is presumed that the figures given below this heading are the maximum pull of the stay wire. On page 187, under the heading "Insulators," with reference to the joining together of insulation made in two parts, any form of cement has a tendency to expand and break the insulators, and it seems therefore a safer plan to have the two parts stuck together with the glaze when the insulators are made. In Appendix V, page 198, the note at the bottom of the table would be improved if the words "for the same temperature rise" were added at the end of the note.

Mr. J. A. MORTON (*communicated*): First, with regard to the Board of Trade figures for windage and factors of safety. As the author says, the windage is taken at 25 lb. per square foot of plane surface, and the factor of safety at 10

for wood poles and 5 for wires. It is obvious that if these figures are assumed to be safe (which is, I take it, the idea of the Board of Trade) for the worst kind of cross-country work in England, then for overhead distributing mains in say, villages or small towns, the figures are much higher than are necessary, because it is impossible for lines run between houses along streets to be subjected to a wind pressure of this description, or to such hard conditions as a cross-country line. If, however, as the author suggests, the Board of Trade is prepared to relax this rule, the rules ought distinctly to say so and give an idea of what relaxations will be allowed in different circumstances. Then in designing and estimating for lines—which some of us do almost daily—we should know better what basis to work on in any particular case. What the rule does in many cases is to make the construction much more costly than it might be, and so keep back developments or jeopardize the success of small undertakings in villages and small towns where a low capital cost is of prime importance. As an example of this unwieldy construction it is only necessary to look at the lines erected at Brumby and Frodingham, where there are huge poles like Ionic columns (carrying a few comparatively trifling wires) placed along the side-walk, filling the pathway and making the streets even uglier than they were. Further, these Board of Trade figures for poles practically prevent the use of a standard single wood pole which is cheap, can be solidly planted, looks well, takes up little space, and allows simple bracket arms to be used. Standard sizes of single poles can only be used with very light lines where this factor of safety and wind pressure have to be allowed for. One is forced to use very stout single poles, which have to be cut down from much longer poles to get the required diameter and are consequently very costly and ugly, or to use "A" poles, which are also costly and take up a lot of space. But "A" poles are of course impossible for distributing mains in streets or roads, and can only be adopted for cross-country lines. In America even across the plains, where the lines are subjected to very strong winds and worse conditions than we have here, the maximum wind pressure is usually taken at 30 lb. per square foot, with a factor of safety of 6 for wood poles. In considering also the flexibility of wood poles one is further inclined to suggest that the factor of safety should be reduced. If we take a 32-ft. stout single Post-Office-size fir pole planted 6 ft. deep, this would break at the ground line with about 29 cwt. applied at the top across the line. The Board of Trade would only allow 1/10th of this stress, viz. 2.9 cwt., and yet this would probably give a temporary deflection of under 5 in., whereas a reasonable deflection for such a pole would be about 7½ in., and would still leave a factor of safety of 6½. Similar criticism might be applied to the factor of safety which the Board of Trade demands for steel poles.

Now with regard to the question of line-wire dips; these are to be worked out for 25 lb. wind pressure and with a factor of safety of 5 at 22° F., ignoring snow and ice. I have worked out the following table, and in column "D" will be seen the Board of Trade dip required under these worst conditions. As, however, wires can never be erected at this temperature with a 25-lb. wind blowing, it is necessary to find out what dip to give the wires at, say, 60° F. with no wind blowing. This is of course a com-

ton. plicated process, as the elasticity of the wire and the elongation due to the temperature rise have both to be taken into account. In column "E" I have worked out the dip which would have to be given at 60° F. with no wind blowing in order that when the temperature falls to 22° F. and a 25-lb. wind blows the dip would be the Board of Trade figures given in column "D." From these figures we may generalize that if the Board of Trade dip is worked out under the worst conditions, then the wires may be safely erected with that dip at any other temperature on a still day.

TABLE.

A	B	C	D	E
Span in Feet	Size of Line Wire	Material	B.o.T. dip at 22° F. with 25 lb. wind pressure, Feet	Dip to be given at 60° F. with no wind to get B.o.T. dip in preceding column when at 22° F. and with 25 lb. wind pressure.
240	1/0 S.W.G.	Copper	4'27	4'47
150	1/10 "	"	2'87	2'60
150	7/0'063 (Strand)	Aluminium (Equivalent to 10 S.W.G. Copper)	5'28	4'70

It will be seen from this table that in the case of a 240-ft. span of 1/0 wire the Board of Trade would require a dip of 4'27 ft. Now if the dip were worked out on the assumption that the worst conditions in England would be 17 lb. per square foot wind pressure at 22° F. with an ice accumulation which had doubled the diameter of the wire, then we should find the safe dip under these worst conditions to be only 2'243 ft. with a factor of safety of 2. I consider that such conditions are about the worst that could be reasonably assumed, and a factor of safety of 2 should be sufficient, because an overhead line is a very flexible and not a rigid structure; moreover, angles in a line add to its flexibility and help to relieve the stresses in the line wire when they are getting high at low temperatures. Even the Hydro-Electric Power Commission of Toronto in Canada in working out the sags for important trunk lines take the worst condition as 17 lb. per square foot wind pressure with $\frac{1}{2}$ in. of ice on the wires at a temperature of 32° F. and a factor of safety of 2 under these conditions. Their conditions, it must be remembered, are much more variable and onerous than ours. In this case the dip, taking into account the elasticity of the wire, would be 3'65 ft. for these worst conditions. This figure is comparable with the 4'27 ft. Board of Trade dip required under the worst conditions in England. I therefore think that the Board of Trade figures for dip calculations are also too high. It will also be noticed in the case of the 7/0'063 in. aluminium strand that the dip comes out according to Board of Trade figures at 5'28 ft.; this

Mr. Morton. makes it practically impossible to use such a wire. It makes the pole abnormally long and the swing of this wire from the vertical under a 25 lb. wind pressure would be about 5'25 ft.; it would therefore be impossible to put two wires in the same horizontal plane, as we could hardly make the cross-arms long enough, even assuming that such a sight (with the wires hanging in festoons) would be tolerated.

Next, with regard to the question of resistances in the earth circuits of horn arresters. The natural impedance of any overhead circuit is $\sqrt{L/C}$, and this varies in practical overhead work between 500 and 250 ohms. In any single horn-gap the resistance in the earth circuit should not be less than twice the natural impedance of the circuit; if it is, then the breaking of the current flowing to earth is liable to set up high-frequency oscillations in the wires and the machinery connected to them. If the earth resistance is much greater than twice the natural impedance it might be too high to afford relief to the line. There are, of course, as is stated in the paper, objections to all spark-gaps; but in this connection I would call attention to an article by Mr. A. W. Burke in the *Electric Journal* in June last* on some new ideas in regard to the horn-gap arrester, where the horn arrester is also made to serve as a choking coil and where the line current itself is taken round the horn of the line side of the arrester; that is to say the arrester is in series with the line, whereas at present it is usual to connect the arrester gap in shunt with the line. It is stated that this type of arrester will even operate successfully on a voltage as low as 2,200, and that owing to the magnetic field being increased by the working current flowing round the horn, the additional increase in the electro-dynamic field is sufficient to allow the arrester to operate without any resistance in the earth circuit, the arc rising and lengthening on the horns so rapidly that the earth current is limited almost instantly. Other arrangements of this form of horn arrester are described for voltages up to 45,000; and it is stated that they will operate successfully without causing a disturbance on the line, that they will dissipate an arc before the circuit-breakers can open, that they require no attention, and that they can be mounted out of doors. It is also stated that they have been in successful operation for the past three years.

With regard to the suggestion of getting the Board of Trade's consent to run high-tension lines along public roads where conditions are suitable, I suggest that this is quite the wrong way to get out of the trouble and delay in obtaining private wayleaves, and that the game is not worth the candle. In most cases the idea is impracticable, because most public roads are already disfigured by Post Office telegraph wires, trolley line poles, and sewer ventilating shafts, etc., leaving insufficient room for high-tension overhead lines in addition. Owing to these existing obstructions, very few high-tension lines could be run entirely along the road-side—parts would certainly have to go across private land, and the trouble here would delay the whole line almost as effectively as if it all ran across private land. There would also arise complications due to inductive effects on the Post Office wires along the same road. Further, our roads wind about, which means numerous struts and stays—as in the case of Post Office

* Vol. 10, p. 530, 1913.

Mr. Morton lines—which add to the cost and in many cases have to be planted in private ground, permission having to be obtained from private owners, with consequent delay. Steel poles strong enough to stand up without staying or strutting might be used at angles, but they are very expensive indeed except for very light lines, and quite impossible on heavy lines. The way out is by legislation making it possible to obtain cross-country wayleaves quickly and on reasonable terms.

Mr. Stubbs Mr. A. J. STUBBS (*communicated*): As the author has referred to Post Office practice, it may be worth while to mention that, besides providing for a factor of safety of 4 instead of 5 for copper wires, the department's calculations make no allowance for wind pressure. The cases, however, are essentially different. Our structures are generally not so exposed because they are short, and failure involves in our case practically no risk to life. Generally, we are satisfied that we get reasonable immunity at reasonable cost. The author's photographs showing accumulation of snow assist materially to illustrate the conditions. It will have been observed that the accumulation is practically of the same dimension irrespective of the size of the wire. Obviously this will be so, as, having once got a rope of snow, say 1 in. diameter, the succeeding accumulation will not be affected by the dimension of the inner core, upon which the accumulation has formed. Mr. Vernier stated that they have tried to provide for this by increasing the gauge of the conductor beyond what the electrical requirements actually demand. We also do this in regard to very exposed positions, but anything less than 150-lb. wire is not much good for this purpose, and to put that size generally where 40-lb. wire will meet the requirements would clearly be too great a premium to pay for the additional security. It may, however, be of interest to observe that much of the destruction wrought by storms on telegraph lines is due to trees falling across the lines—a condition that no factor of safety can be expected to provide against.

Mechanical design (page 179).—A- and H-poles rarely fail as structures except when, owing to the collapse of wires on one side of a pole, the strain of all the wires on the other side is suddenly thrown upon the pole. In this case of course the strength is only that of two single poles. The author's figures for transverse stress seem to suggest that untrussed H-poles should be very sparingly used. With reference to the spacing of H-poles (page 182), it may be observed that when poles are braced together with parallel centre lines, the clearance between, being wider at the top than at the bottom, causes them to appear splayed out—a rather unsightly effect. We construct with the inner sides parallel.

Effective area of single wires for resistance to wind.—The author adopts 60 per cent of the resistance due to a plane area equal to the diameter multiplied by the length of the wire. The Post Office practice is to take 66⅔ per cent. At the request of the Post Office Engineering Department the National Physical Laboratory has recently looked into this question. The experiments confirm that the pressure is proportional to the square of the velocity of the wind, and the observed effect upon wires 30 mils and 194 mils in diameter show that the Post Office calculations are in fairly close accord with the facts; but the figures work out rather too low. It would appear, therefore, that the

2/3 factor is to be preferred to 3/5. This, however, is Mr. Stubb's scarcely the occasion for going more closely into the details of the experiments.

Insulator pins (page 180).—For practical purposes our method of testing by load applied on the insulator appears more convenient. The ordinary steel spindle (¾ in.) breaks at not less than 2,000 lb., and the terminal spindle (¾ in.) at not less than 3,500 lb.

Steel channel (page 180).—No doubt the author has noticed that the length factor has not been defined where he refers to ¾ in. deflection. I think also he will find that his formulae want checking—perhaps the factor of safety has not been allowed for.

Creosoted poles (page 183).—The Rüping process has undoubtedly come to stay; but tests which we made some years ago show that the Powell process has little to commend it—the poisoned saccharine matter was found to be washed out after a comparatively short period of exposure. It is a very valuable facility where slotting and boring can be done before creosoting. Poles often rot through moisture getting in at the arm slots, in spite of the treatment of any kind of cut that is made with creosote. We get many good illustrations of the difference that is made by the creosoting process in such connection—for instance, when the core of a pole has rotted there are spurs of sound timber where cracks existed before the creosoting was done, while the sound timber is reduced around the cracks that have formed after creosoting.

Stays (page 184).—I think that the painting of stay threads with the preservative mixture should be made a rule, without exception. Galvanized threads are very unsatisfactory, and we have found it best to have the threads cut after galvanizing.

Telephones (page 190).—The high-tension telephone shown on the screen did not appear quite to tally with the author's description in regard to hearing tubes. If, however, hearing tubes are actually used, our early experience with the Gower telephone may be of interest. We found that the rubber tubes became defective after a time, and seriously depreciated the speaking efficiency. A ready test of the condition of the tubes consisted in making one convolution with a tube, and blowing smartly into the ear-piece. If the tube was sound, it gave a sharp whistle.

I am a little sceptical as to the case made out on page 192 for the abolition of guarding on the score of equipment of lines with automatic protective apparatus, especially in view of the recognized possibility of a shut-down of the line by the operation of crows, as described on page 186. It is believed that in such circumstances the switchboard attendant resets the circuit-breaker and perhaps holds it momentarily in position so as to burn off the trouble. Such resetting of the safety devices seriously discounts their protective value even if, as was suggested by one speaker, their inconvenient sensitiveness has not been already corrected with the aid of string.

Mr. H. BRAZIL (*communicated*): There are one or two Mr. Brazill points in connection with the protection of the line that I should like to discuss, as I am afraid I am not in agreement with the author upon this matter. The particular sentence on which I wish to base my remarks is the following: "The author is strongly of opinion that any form of arrester which involves a spark-gap is wrong in principle,

because of the high-frequency oscillatory disturbances caused by a spark in a circuit." In a footnote to his paper the author quotes Mr. Duddell's Presidential Address in support of his argument, but I also wish to quote this address in support of my side of the question. I do not wish to suggest for a moment that Mr. Duddell's address is contradictory, but I venture to think that the mistake is Mr. Welbourn's in grouping together all spark-gap arresters, whether they break the circuit by means of a spark or by means of an arc. It is the difference between an arc and a spark that I wish to discuss, and on this point I will quote Mr. Duddell as follows: "The fundamental difference between an arc and a spark is that in the arc the electrodes are being continuously volatilized, and the vapour of the electrodes takes part in the passage of the electric current. The spark, however, is generally of an intermittent or transitory nature, the electrodes are not appreciably volatilized, and the current is largely transferred through the air." Throughout his address Mr. Duddell warns us that we must not break circuit rapidly as when this is done (and this is what I call a spark) serious pressure rises occur. Whereas, on the other hand, I would again quote Mr. Duddell: "I have not yet come across a well-authenticated case in practice of an arc acting as a musical arc and producing dangerous pressure rises." To my mind, breaking circuit by means of a spark in the one case, or by means of an arc in the other, is analogous to breaking circuit with a quick-break switch, as against breaking circuit through a continuously increasing resistance, and I need scarcely point out the advantage of the latter proceeding.

Mr. Welbourn condemns horn arresters entirely, but I should like to quote a few things in their favour. For 10 years past I have had experience with a system having 50 horn arresters installed, and I can testify that far from their being a source of trouble to us they have been very beneficial. Before these were installed we had a very large amount of trouble with surges, and this was very greatly reduced when the horn arresters were installed. Further, in one case where, owing to a mistake, a man left the horn arresters disconnected on a certain part of the system, several machines broke down, but after the horn arresters were reconnected these troubles disappeared. These horn arresters have indicating arrangements attached, and to my knowledge they have discharged over 1,000 times, relieving the system without causing trouble. I would also call attention to an article by Mr. W. A. Coates in the *Electrical Review** for 26th December, 1913, in which he gives particulars of some very large systems working with air-break switches and horn lightning arresters. The main contacts of the switches are first broken, and the arc is drawn out on a pair of horns, so that the action is similar to a horn arrester. Oscillograph records of a switch opening a load of 1,000 kw. at a pressure of 33,000 volts show no disturbance of potential; and a subsequent test in which a load of 8,000 kw. was switched off gave similarly good results. This I believe to be entirely due to the gradual breaking of the circuit caused by the continually increasing resistance of the arc as it grows longer. I am convinced that where trouble has been experienced with horn arresters on overhead lines it

is very often due either to the fact that no resistances are put in circuit with the horns, or that the resistance is not properly designed or of sufficient capacity. It is essential that the resistances shall be able to stand a very heavy load for a short time; and of course they must be absolutely non-inductive. A considerable number of such resistances of the carbon-powder type have been installed on the Cornwall Electric Power Company's system, and are working very satisfactorily. If we accept Mr. Welbourn's condemnation of spark-gap arresters, this eliminates practically every type, including the electrolytic arresters, which have a horn in series with the aluminium cells, and which are so largely used in America. The only type that is left is the Moschick condenser. While quite admitting that these are valuable for dealing with surges of very high frequency, I would point out that they are useless when a surge has a frequency of, say, 500-1,000 \sim per second, a very usual frequency for surges caused by "earths" and short-circuits. (See Messrs. Creighton and Sprong's paper in the July, 1909 number of the *Proceedings of the American Institute of Electrical Engineers*.) I think it is quite clear that the danger to be avoided in lightning arresters is that of making the rate of change of current very great, that is to say, switching-off rapidly; and I would suggest to Mr. Welbourn that arrester horns with a suitable resistance in circuit will not break the circuit quickly, and therefore should not give trouble due to high-frequency oscillatory discharges.

Mr. C. WADE (communicated): I was pleased to see the author's favourable remarks *re* the cost of overhead lines and the use of wood poles. I was also glad to note last spring that the Board of Trade had reduced their wind-pressure requirements, thus allowing the size of poles to be slightly decreased. It always seems to me that the difficulty of obtaining wayleaves is one of the most serious troubles preventing the greater use of overhead lines. As the author says, the law relating to the same should be revised, and I think the granting of wayleaves should be made compulsory. With regard to preserving timber poles, I agree with the author's remarks *re* the preparation of the same, but I rather doubt the efficacy or necessity of the tarring-over of the pole butts, etc., or of the creosote in the ground at the foot of the pole. The Rüping process of creosoting, of which my firm were practically the pioneers in this country, appears to be giving universal satisfaction and superseding the old Bethell process. There is no doubt Rüpingized poles or cattle-guards can be painted a few months after erection, and the Post Office and my firm are experimenting to ascertain the most suitable paint. I should never think the Powell process or any other process will be a serious rival to creosoting in this country. I investigated this process some years ago, and its advantage seemed to me to be in its claim to withstand the attacks of white ants in tropical climates.

The question was raised at the Yorkshire Local Section discussion as to the relative strength of "A" and "H" poles. This point has been raised several times, and I have considered the advisability of making tests. The strength of H-poles, however, would appear to be entirely governed by the amount of bracing and the distance apart of the members; and as it would mean such extensive tests to include poles used by various

* Vol. 73, p. 1043, 1913.

* Vol. 28, p. 867, 1909.

Mr. Wade.

engineers, I have not done anything up to the present. I will, however, consider the matter. I have generally assumed that a properly made H-pole as generally used is of about the same strength as an A-pole, which is very similar to what Mr. Welbourn said.

Mr. Fox.

Mr. E. J. FOX (*communicated*): I am unable to agree with the author's statement as to the merits of steel and wood poles. Mr. Welbourn seems to some extent to condemn steel poles because he has come across instances where steel tramway poles have corroded in a comparatively short time. It is generally accepted that under certain conditions iron and steel require more careful protection than under other circumstances. As an instance I might mention a corrugated iron roof covering an area of about 10 acres and exposed to the atmosphere both outside and inside, the works in question being in this respect similar to a railway-station. The outside of the roof requires painting about every two years in order to protect it from corrosion, whilst the inside has not been touched for 14 years, and is to-day in as good a condition as when new. In one small portion where locomotives run underneath the roof the sulphurous discharge has tended to corrode the inside of the roof immediately above the discharge from the locomotives, whilst the adjoining portion—as already mentioned—shows no signs of deterioration after 14 years' use. On one important point engineers and buyers can ensure their steel poles having the longest possible life, namely, by excluding high-tensile steel, of which poles are sometimes made. Most chemists will agree that high-tensile steels tend to corrode more quickly than either wrought iron or mild steel; and this is probably due to the higher percentage of manganese and carbon present in high-tensile steel. Mild steel with a tensile strength not exceeding 24 to 28 tons per sq. in. will give the best results in the direction of the minimum tendency to corrode. Engineers would do well to specify the steel of which their poles are made to fall within this figure. The following shows the percentage of manganese and carbon present in various average samples of iron and steel of which these poles are made:—

	Iron	Mild Steel.	High-tensile Steel.
Manganese ...	0.030 %	0.320 %	0.750 %
Carbon ...	A trace	0.100 %	0.320 %

Mr. Trechmann.

Mr. H. K. TRECHMANN (*communicated*): This paper offers very little scope for comment. It would not have been without interest, however, had the author added a section on the probable direction which future developments will take. It will be noted that he justifies the use of overhead lines by their cheapness, and shows that by the extended business resulting from their use benefits are reflected upon practically all branches of the electrical power supply industry. Here then may be seen where further developments are to be expected. To benefit the community as a whole and the electrical industry therewith, the price of electricity must be reduced (*vide* Dr. Ferranti and others); and in effecting this desirable state of affairs the cost of all items concerned in its production and distribution must receive attention. Both Continental and American practice are to be regarded as considerably ahead of English practice in respect to overhead work generally, and in America especially there have been

marked developments in connection with apparatus for outdoor use, such as overhead air-break switches, and in fact all apparatus necessary to equip complete outdoor sub-stations. Indications are not wanting in the paper that English practice will, in order to make progress, follow to some extent at least the example of American and Continental engineers. For instance, the terminal pole in Fig. 12, with its special housing for Moschick condensers, may be regarded as a small step in that direction. The lantern slide showing an overhead transformer is also a case where overhead switching might very appropriately be employed. Mr. Trotter does not regard the placing of transformers on poles as good practice, but if the electrical conditions could be made to correspond with those of transformers in sub-stations there would be no essential difference between the two situations other than that of cost. Overhead switching would appear to be the only medium for obtaining proper control of transformers placed on poles, and though they are not beautiful they certainly are "load," and therefore not to be despised. In practice also cases frequently occur where switching arrangements are desirable, but where the circumstances do not justify the cost of building and equipping sub-stations. As regards the protection of lines from surges, the system adopted by Messrs. Merz and McLellan is stated to be both effective and cheap, although as the amount of added insulation appears to be something between 20 and 30 per cent of the total on the high-pressure side of the transformer, it might have been expected that some considerable increase in both size and price should have taken place. It would be interesting to know if any figures are available as to the effect on the reactance of the transformers when fitted with reinforced insulation in the manner described.

Mr. E. T. DRIVER (*communicated*): There are many technical advantages accruing from the use of aluminium conductors other than that of economy. In the early days of overhead transmission the line voltage was limited by the insulation of the transformers used in conjunction with the line. Such transformers then began to receive more attention, and with the advent of the oil-immersed transformer of improved design and more reliable insulation the limiting factor in line voltage became the line insulators. These in their turn were improved to meet the requirements called for, and finally with the replacement of the pin-type insulators by those of the suspension type, pressures of 150,000 volts have been rendered possible. Several lines of this voltage are now in the course of erection. With the employment of such voltages, however, another difficulty has been encountered, namely, corona loss. This subject has been exhaustively studied by Mr. F. W. Peek, who has shown that the corona loss is a function of the diameter of the conductor. Now for equal conductance the diameters of aluminium and copper stranded conductors are in the ratio of 1.29 to 1, and Mr. Peek's experiments have shown that the critical voltage for the aluminium conductor would be some 20 per cent higher than for the copper conductor, due to the 29 per cent greater diameter of the former. As an example, copper conductors of 0.06 sq. in. section with a 10-ft. spacing would give a corona loss after a pressure of 86,000 volts had been reached, whereas with equivalent aluminium conductors the corona would not occur until a pressure of 106,000 volts had been reached. Assuming

a line pressure of 100,000 volts, there would be a loss with the copper of some 3 kw. per mile of single-circuit line, whilst the aluminium line would give no loss at all from this cause.

Turning now to lower line pressures, such as are used in this country; where such extra-high pressures as above mentioned would not be commercial propositions, owing to the very short length of the lines, aluminium will again be found to possess advantages over its heavier competitor. It has often been stated that the 20 per cent greater diameter is a serious drawback on account of the larger wind pressure. Under the Board of Trade Regulations overhead conductors must be erected to withstand a wind pressure of 25 lb. per sq. ft. with a factor of safety of 5 at the minimum temperature. With a conductor of 0.1 sq. in. the ratio of wind loading to the weight of the conductor itself is 4.3 to 1; but with a conductor of 1.0 sq. in. this ratio becomes 1.3 to 1, and it will be found that the deflections under certain conditions of wind and temperature are often considerably less with aluminium than with copper, especially on conductors of over 0.5 sq. in. equivalent copper section. As tending to offset this 20 per cent increase in lateral wind pressure, it must be remembered that the lighter conductors predicate approximately 20 per cent less longitudinal pull in the line than on the equivalent copper line, thus making it feasible to employ a supporting structure of slightly different design, and costing not much in excess of those on the copper line. It will thus be seen that aluminium can advantageously be employed both on low-tension and extra-high-tension systems; and although there would appear to be a larger field for this latter type, which allows long spans and flexible or elastic tower work, such as we cannot employ in this country. Yet the fact must not be overlooked that many of the largest schemes of this type abroad have been and will be engineered from this country. Another point sometimes put forward is that the self-induction of aluminium conductors is greater than that of copper conductors. This, however, need not be so. In the first place the self-induction is a function of the ratio of the conductor spacing (S) to the diameter of the conductors (D); and consequently for any given value of this ratio (S/D) the self-induction is constant. The larger deflection of the aluminium conductor of course necessitates a larger spacing on the cross-arms, but D is increased as previously stated by 20 per cent. The increase of S is not nearly so much as this in the majority of cases; the net result being that the value of S/D for aluminium may be the same as for copper, and even less under certain circumstances. Next, considering capacity, which is a function of D/S , this may possibly be larger for aluminium than for copper, but in most cases capacity may be neglected when considering the regulation of the line, so that there is no reason why the pressure regulation of an aluminium line should not be as good as that of the equivalent copper line.

With regard to steel supporting structures, those of the tubular type would appear to possess several advantages over these of the lattice type. For equal strength the tubular structure is much lighter and therefore cheaper, and experience up to the present seems to indicate that the tubular pole has a longer life than the other type. One objection is that firmer foundations are required, and in certain soils it may even be essential to employ concrete

foundations. This would, however, probably be necessary only at dead-ends and sharp bends in the line. Of late years on the Continent and elsewhere reinforced concrete poles are being employed, with, I believe, quite satisfactory results. Perhaps the author would give a few particulars of this type of structure—as regards its suitability or otherwise in connection with high-tension overhead transmission lines.

Mr. W. SLINGO (*communicated*): I am glad to learn that the work of the Post Office engineers is so much appreciated; and I venture to congratulate Mr. Welbourn upon the production of a paper which contains a vast amount of useful matter. There are a few points on which, however, I should like to make some observations. The first is on the question of wayleaves. He remarks that the Postmaster General possesses certain powers, which are described as being "so cumbersome as to be almost useless." Further on he asks for somewhat similar powers. Let me say that although the Post Office would like the procedure to be more certain and expeditious, the powers are nevertheless of considerable value. This is clearly demonstrated by the fact that apart from the lines acquired from the late National Telephone Company, and those which run along railways, the vast majority of the open lines are on public roads. The first Act of Parliament conferring such powers was passed in 1863, and several other Acts have since been passed to extend them; so that it has taken just 50 years to obtain the present powers, inadequate though they be. That being the case, and remembering that the telegraphs have been under the control of a State Department for 43 years, I fear that the task of such power engineers as may set out to secure statutory powers for their lines will be one which will tax their energies for a few generations. The Post Office might even object that the roads are likely to be inadequate to meet its requirements; but supposing that such a claim could not be sustained, the fact remains that the roads, particularly those leading to London and a number of the larger provincial towns, are now so fully occupied that there is little, if any, room left. The Post Office is already engaged in carrying out underground work along many of the highroads because of its inability to find room above ground. It is, however, somewhat difficult to understand why Mr. Welbourn should desire to utilize the roads unless it be that he desires the power as a lever to secure more moderate wayleave rentals. It is certain that owing to the sinuosities of the great majority of roads, more particularly of those minor roads which I imagine would be most likely those upon which pole lines would be erected, the extra constructional cost involved in the longer copper conductors would more than neutralize any saving which might be made on the wayleave account. But even in the matter of wayleaves I doubt whether there would be any saving. In the course of the discussion one of the speakers said that statutory powers were desirable because the capitalized wayleave rentals amounted in some cases to as much as £100 a mile. I am sure of this, that if such a rental value is not even an extreme case, but only an average case, any line erected under free wayleaves along the roads will involve wayleave rentals for stays and other strengthening fixtures in private property adjoining the roads, which will amount to at least a similar amount. The windings of the road

Mr Slings-

and the need for preventing accidents will be quite sufficient to account for this. Again, a long straight unstayed line is usually a weak one; the Post Office finds it necessary to stay such a line pretty freely, particularly if the ground be at all soft. The special advantages which road lines possess over field lines are the greater security of their tenure, the greater facilities available for their development and maintenance, and the better opportunities for their inspection; but all these can and should be bargained for in the course of the wayleave negotiations. I am afraid the risk of injury to life and property would be regarded as too great to permit of the erection of power lines along the roads. There would also be the risk of contact between the power lines and other conductors, telegraph, telephone, police and water circuits, etc. It should not be forgotten that while the risk of injury from the high-tension circuits to passengers proceeding along the road can be limited to a very brief period after a line has been blown down, the risk to the distant telegraph and other offices is continuous. The discharge may have lasted just long enough to set the place on fire, or it may have proved fatal to a number of operators who would have no such warning as a user of the road might be expected to have. Moreover it is not at all an unusual thing for a line to be blown over without either the poles or the wires breaking. In that case the danger would be even more prolonged. I fear, therefore, that the Post Office could not view with equanimity the prospect of parallel telegraph and power lines along the same road.

On the question of factors of safety Mr. Welbourn is inclined to criticize the factors adopted by the Post Office. Evidence that they are quite adequate so far as poles are concerned is provided by the fact that a pole is rarely broken. It should be borne in mind that a Post Office wire never exceeds $\frac{1}{4}$ in. in diameter and on main lines is usually somewhere between $\frac{1}{8}$ in. and $\frac{1}{2}$ in. On local lines the wires are still smaller. When these wires break they usually do so singly, and every one that breaks in this way reduces the risk of damage to the pole. The only occasion when the whole, or a considerable proportion of the wires, break simultaneously is when a tree falls across the line; no factor of safety, however high, is proof against such contingencies. When such an accident happens there is great risk of damage to the line for a considerable distance on either side, but this is avoided by keeping a good look-out for decaying trees, and by the fairly free use of longitudinal stays—stays, that is, in a vertical plane parallel with the vertical planes of the wires. The Post Office factor of safety of 4 for wires is usually found to be adequate, but in exposed situations it is the practice to increase the factor to 6. The principal cause of trouble is clinging snow; this only happens very occasionally. To increase the factor generally, as suggested by Mr. Welbourn, would mean that in the summer months the sag would be so great as to cause the wires, owing to a slight want in uniformity (such as might be caused by a joint), to come into contact, and without any consequent advantage, for when snow adheres and subsequently freezes and is then followed by wind necessary to cause destruction, a factor of safety of 20 would be insufficient.

The author assesses the life of creosoted poles at 35 to

50 years. I think he is too sanguine. He makes the saving clause that they shall be left undisturbed. Even in such circumstances 35 years is too long for an average figure, and when we take into account such contingencies as premature decay, compulsory removals due to wayleave difficulties, and inadequacy owing to the growth of the system, the effective life is more nearly 20 years. That at least is the figure arrived at by the Post Office, and covers several thousand poles, most of them erected on public roads. The Post Office has been in touch with Ripingized poles for some years. It is too early to say yet whether the process is less effective than the Bethell process, but there are good indications that such is not the case. The process has, however, the advantage that the poles can be painted several years sooner than is the case with ordinary creosoted poles. The author advocates the slotting, etc., of the poles prior to the creosoting—no telegraph engineer would advocate such a policy. Apart from the fact that one never knows how many slots, etc., may ultimately be required, it should be remembered that poles are not turned out on a lathe, that they are not, even the best of them, symmetrical, and that it must always be left to the constructional engineer and his foreman to determine which way the pole shall stand in order that the line may be properly trimmed. I do not like the idea of farring the lower portions of creosoted poles. It looks too much like the gilding of gold and the painting of lilies. It is neither useful nor ornamental. The author says that an angle (or "corner") pole should be so placed that the plane of the wires shall bisect the angle made by the wires; but this is of course only true when the spans on either side are of equal length.

Concerning aluminium, the Post Office experience is that owing to its lightness it is more liable than copper to be blown across the road. The possible advantages of aluminium in certain neighbourhoods are, however, worthy of closer attention. I have known copper wires to become so corroded in 18 months as to be incapable of supporting their own weight. It is doubtless well known to members that the strength of hard-drawn copper is little more than skin deep. Swinging into contact rarely happens if the wires supported by any one arm are of the same material and gauge and free from joints. In a heavy wind it is quite an ordinary thing for the wires to be blown into a horizontal plane. The great advantage of white insulators is that it can easily be seen whether they are clean or foul. All forms of dirt become fairly good conductors, particularly in damp weather, and the loss from this cause may easily be very appreciable.

Professor E. W. MARCHANT (*communicated*): On page 181 the author describes a graphical method for finding the losses in the line. A much simpler way of calculating them is to find the current in the line and the resistance of each line, and from these to calculate the power lost. A graphical method is convenient for estimating the pressure-drop on the line, but even in this case it is quite as easy to calculate the drop. I wish the author had conformed with the recommendation of the International Electrotechnical Commission and drawn his diagram in Fig. 3 so that the vectors rotate counter-clockwise. The equation for the breaking stress in tons per square inch, $T = 30 - 20D$, must obviously be limited in its application,

Profes
March

and it would be useful if the author could give us the range of values for which the formula holds.

With regard to aluminium lines, the practice in America seems to tend towards the use of copper. Aluminium is never used near the sea on account of corrosion. It is a metal of very variable qualities and it appears to be difficult to find specimens which will behave in a perfectly uniform way. Professor Wilson described at the meeting of the British Association some results which he had obtained at King's College with commercial aluminium exposed to the atmosphere. One interesting point is that the variation in resistance in specimens first exposed 2 years ago is greater than it was 12 years ago when the atmosphere was much more smoky. This result is probably due, as he points out, to small variations in the impurities in the metal. I do not understand the reason for the difference in spacing recommended for 20,000-volt and 10,000-volt lines. Electrically there is no reason why the distance between them should not be 3 in. instead of 3 ft. at 20,000 volts. The only factor which has to be considered is the risk of the wires touching, and this is as likely to occur on a 20,000-volt line as on one working at 10,000 volts. The rule mentioned by Mr. Peck of 1 ft. spacing for every 10,000 volts, with a minimum distance of 2 ft., seems to be quite satisfactory. Very little trouble has been experienced due to the swinging together of the wires, even on long spans. In this connection I may mention that the longest span I have seen is one of about 3,000 ft. across the straits just outside San Francisco. Steel wires had to be used in this case in order to provide adequate strength. The question of pin versus suspension-type insulators is almost entirely an economic one, and I am inclined to think that the suspension type becomes cheaper at a considerably lower pressure than the author suggests. The limit which I have found with the figures at my disposal is about 30,000 volts. With regard to the use of Mosecick condensers as lightning arresters, I should like to ask whether any trouble has been caused by static charges. The condenser provides no path for the static charge and under heavy atmospheric disturbance might easily be broken down.

Mr. B. WELBOURN (*in reply*): I should like to thank the various speakers for the cordial reception which they have given to this paper, and I am pleased that the discussion has brought out such a number of practical points and so much useful information. The suggested alterations in phraseology, etc., which come from Mr. Donkin are good and I must ask members to be good enough to alter their copies of the *Journal* as the paper has already been printed. In Appendix VIII the coefficients of expansion of aluminium should be corrected to read 0.0000245 and 0.000036. The printers have my sympathy in the difficulty of setting up such large numbers of figures.

The discussion in London and at the provincial centres will have demonstrated to the Council of the Institution that there is a genuine grievance on the part of statutory undertakers in regard to wayleave difficulties, etc. As Mr. Woodhouse says, the subject has been ventilated before the Institution for several years without any assistance from the Council being forthcoming. The task of persuading the Government to attempt to alter inconsistencies in the law of the wayleaves, etc., and to put statutory and non-statutory undertakers on an equal footing, is one which

the Council might well deal with, instead of leaving the matter to be fought out by a few power companies. Representations on the subject would come with greater force and authority from this Institution speaking on behalf of several thousand members.

Mr. Slingo's remarks on wayleaves come very opportunely and indicate clearly the difficulties to be faced. It is probable that the "spade-work" already done during the last 50 years by the General Post Office will be of the greatest value to this Institution if the Council decides to deal with the matter. There can be no doubt that they would welcome Mr. Slingo's co-operation and would be glad to have the benefit of his great experience. I am glad of the opportunity afforded to me by Mr. Slingo and other Post Office engineers of explaining that the wayleave difficulties referred to are those in connection with "work across country," as stated in the context. The local authorities afford many facilities to the Post Office for the erection of lines along roads, and I do not suggest that high-tension lines should be run except under very unusual circumstances along roads already occupied by the Department's wires. There are many difficulties in erecting lines along roads, but the privilege of being able to use the roads for high-tension lines would sometimes be of the utmost value for "short-circuiting" difficult land-owners and for giving a supply to outlying farms, etc. It is suggested that this matter (among others) might be dealt with by appointing a Transmission Lines Committee who would advise the Council on all matters affecting overhead lines and who would draw up a report on the immediate difficulties and proposals for dealing with them. I feel sure that it will be gratifying to Mr. Trotter to learn from the discussions in London and the provincial centres that practically all the engineers who are responsible for the operation of high-tension lines are satisfied with the factors of safety prescribed in the present regulations of the Board of Trade. I am inclined to think that if these are ever revised and put on a more scientific basis they will be based, as far as the conductors are concerned, on the limit of proportionality and not on the ultimate breaking stress. This is equally fair for copper and aluminium.

I was very interested indeed in what Commander Schwann said with reference to airships. From the supply authority's point of view there is an obvious answer to the attitude of the Admiralty, *i.e.* that the supply authorities would be delighted to put all their high-tension wires underground if that Government Department would give them a subsidy that would recoup them for the extra cost. This question of damage to aeroplanes and airships by high-tension wires is a new point to us, and a method of indicating their position will require very careful consideration; possibly when we have had time to think it over we shall be prepared to make suggestions which will go some way towards meeting the Admiralty's views. The solution will be difficult if provision has also to be made for indicating pole routes during the hours of darkness. I think that possibly some restrictions will have to be imposed in regard to the erection of any overhead lines, especially high-tension lines, within a radius of, say, 5 miles of Government air stations on the coast. We must all be prepared to place patriotism before other considerations, and not to do anything which will in any way interfere with our national safety.

Mr.
Welbourn.

Mr. Woodhouse.

Mr. Woodhouse and other speakers have raised the question of the cost of overhead lines and wayleaves. The latter aspect of this was dealt with by Mr. Vernier in his remarks. Figures as to cost are necessarily general, and will vary according to local conditions. Figures supplied to me show that across difficult country where haulage and wasted walking time are large items of expense the first cost of a line, such as that for which figures are given in the paper, has been as much as £1,600 per mile. I think, however, that my figures represent average conditions. They indicate that the principal savings are to be made in using overhead construction where the voltage and the kilowatt capacity are high. Mr. Vernier supported the view which I interjected into my opening remarks, that at 3,000 volts the saving to be made by using overhead construction in preference to underground cables is frequently insufficient to make it justifiable commercially. The same remark also applies to some of the low-pressure overhead schemes which have been carried out.

With regard to conductors, I have tried to make it clear in the paper and by explanatory remarks that at our working pressures (into which corona questions do not enter) the total overall cost should determine the choice between copper and aluminium. I quite recognize the force of the remarks on this point and I agree that the advantages and disadvantages must be fully weighed in each case, always bearing in mind that a small increase of reactance on overhead aluminium lines is not wholly a disadvantage in that it helps to limit the effects due to the failure of insulators, etc.

Mr. Jacob called attention to a recent article in the *Electrical Review* on the Rjukan Foss scheme in Norway, in which the statement is made that aluminium conductors when kept alive do not gather snow. This question of the collection of snow by copper and aluminium was discussed before this Institution two or three years ago when two papers dealing with American practice in overhead lines were read; and in his reply Mr. Borlase Matthews was emphatic that American experience showed that aluminium and copper collect snow equally. I welcome this statement in the *Electrical Review*, coming as it does from a reliable authority. On the other hand, there is reliable evidence that the aluminium conductors on the Sherburn lines in Durham did collect sleet even when kept alive. Possibly the aluminium-producing companies will consider the desirability of engaging an independent expert to experiment on this question. I would suggest that investigations should be carried out with aluminium and copper wires which have been erected for some years, as well as with new wires.

I regret I cannot agree with Professor Marchant that aluminium is never used near the sea on account of corrosion. I looked into this matter rather closely last year and came to the conclusion that the corrosion of aluminium is usually to be associated with the metal in the form of an alloy not protected from air and moisture, or else with the presence of excessive quantities of impurities. The aluminium which is used for British overhead lines usually contains not less than 99.30 per cent of pure metal,

and I should not hesitate to use it near the sea. I shall be pleased to show Professor Marchant a sample of aluminium wire which is in my possession after being in use near the coast for about ten years. As stated in the paper, our knowledge of the production and working of aluminium has increased rapidly during the past three years. It is this knowledge which has led me to doubt the present commercial value of the interesting tests which Professor Ernest Wilson has carried out at King's College. I am well aware of the character of the smoky atmosphere above the College after spending more than three years of my student life there, and I am glad to think that no aluminium or copper is likely to be erected on high-tension lines in this country where it would have to meet such severe conditions. It would be very useful if Professor Wilson would repeat his experiments in country air and publish the results.

Professor Marchant and other speakers have queried the minimum spacing of conductors suggested on page 185. These minimum spacings are founded on no general law, but on a considerable amount of experience in this country and elsewhere, and are mainly determined by the sizes of pin insulators and the clearances necessary at the points of support. Examples of spacings found necessary on various lengths of span in this country have been given on pages 182-3. A good deal of experience is required to settle the spacing necessary in each case.

The equation $T = 30 - 20D$ for the breaking stress of copper in tons per square inch is applicable to all the sizes of wires in Appendix IX. For a full treatment of the subject reference should be made to Mr. D. R. Pye's paper on "The Mechanical Properties of Hard-drawn Copper," which is mentioned in the Bibliography on page 104 of my paper. I am sorry that it is too late to adopt Professor Marchant's suggestion that I should alter Fig. 3, as the number of the *Journal* containing my paper has already been issued.

I am much obliged to Mr. Trotter for pointing out an apparent inconsistency in connection with the glaze of insulators. The first reference is to rigid clamps breaking the glaze and causing insulators to fail *some years ago*. In the period which I had in mind, the importance of having high-tension insulators vitreous throughout was not always recognized, and too much depended on the soundness of the glaze. I showed such an insulator at the meeting. The necessity of complete vitrification is now well understood, and emphasis is laid on it in the paper. Attention to this point and to that of colour, coupled with the tests set out in Appendix XII, should give quite satisfactory results.

Mr. Kay showed a series of slides of the special steel pole which his firm is developing. It is a very interesting type, and I wish it success, but I fear it does not escape some of the objections which I have urged against steel if it is intended for use in districts where smoke and other corrosive agents exist. Special precautions are needed to preserve the steel stay wires on which so much depends in this design; and one also wants to know how the interior of the steel members is to be prevented from rusting. The external painting of steel poles every two or three years is a serious item of expense, and, in addition, the supply of energy must be interrupted while the tops of the poles are being done. It is difficult to imagine this or any

Mr. Wilson.

* W. T. TAYLOR. "Modern Long-distance Transmission of Electrical Energy." *Journal I.E.E.*, vol. 49, p. 510, 1911.

R. B. MATTHEWS and C. T. WILKINSON. "Extra-high-pressure Transmission Lines." *Journal I.E.E.*, vol. 49, p. 562, 1911.

other tubular steel pole having the life of a well-croseted wood pole until the all-electric era is with us, and smoke, etc., are banished. I will readily agree with Mr. Kay that he is making provision for some of the obvious difficulties; but when I compare his strong recommendation of high-tension steel with the equally strong condemnation of it which comes from Mr. Fox (a steel-tube manufacturer), I am more than ever convinced that it is difficult to make out a good case for steel poles (lattice or tube) in most parts of the United Kingdom. Of course steel or wrought-iron structures must be used on railways, etc. It is a case of *force majeure*; but the bridges, etc., are a source of constant worry to the engineers who are responsible for their upkeep, and the frequent cleaning and painting are very costly. Evidence of this dissatisfaction with steel is forthcoming from the increasing use of ferro-concrete structures. Poles of this material have been used for some low-tension lines in this country; and while I do not know of any high-tension line employing them, I think they are certainly worthy of serious consideration. Mr. Fox has asked me a question about roof maintenance. This is not directly comparable with pole—and especially tubular pole—maintenance. In one case we are considering corrugated iron which presumably starts its career with a new coat of galvanizing, and yet requires to be painted externally every two years. In the case of lattice steel poles, the two-year cleaning and painting are just as necessary, while tubular poles cannot even have this attention inside—I do not think anybody will dispute that they need internal attention despite the original coating of Angus Smith's solution. I should say that Mr. Fox's roof is satisfactory to him because of the original galvanizing and the frequent coats of paint. It would be instructive to know what this has cost.

Mr. Morton's contribution is particularly acceptable in so far as it discusses the question of the factor of safety and its bearing on practical construction work and design. A full consideration of the inner meaning of the lantern slides showing snow-covered conductors, and a knowledge of the effects which have resulted during a gale, have led me to the conclusion that no case can be made out for reducing the Board of Trade's prescribed factors of safety for overhead conductors on high-tension lines on which continuity of supply is usually more important than a possible saving of a small percentage in the first cost. It also follows that where continuity of supply is the paramount consideration, e.g. the supply to a city such as London or to any big town, or even to an electrochemical works, the transmission line must consist of duplicated underground cables, which are exceedingly reliable and can be protected against mechanical injury. Although the question of reducing the factors of safety on low-tension lines does not immediately arise on this paper, I am in sympathy with his argument so far as it relates to them. The problems and dangers on high-tension and low-tension lines are not the same in every particular.

I agree with Mr. Nelson that factors of safety might form the subject of a paper. May I suggest to him that he should undertake it? I think he might find that for high-tension work a better case could be made out for raising than for lowering them. He has made a good point as to the advisability of using side stays for preventing the swinging together of the conductors in certain cases. Fig. 14 was intended to be diagrammatic and I agree that

the leakage path should in practice be as long as possible. Mr. Four insulators at transposition points may be, and frequently are, used, but the arrangement is not so neat as that shown. The final choice must depend on the local conditions, as in many other features of overhead-line construction.

I welcome Mr. Stubbs' and other communications which have only reached me in time to receive brief treatment before my reply is published in the *Journal*. Mr. Stubbs has given us the benefit of the extensive experience of the Post Office, and his points will be carefully noted by transmission line engineers. I may explain that the $3/5$ factor is that stipulated by the Board of Trade, and it was probably settled in conjunction with the prescribed factors of safety. The length factor for the steel channel had not been overlooked. The formula can be used for channels as shown in Fig. 6. Mr. Stubbs' point as to guarding was partly dealt with by Mr. Trotter. While a good deal of guarding might be abandoned, it was not my intention to suggest that there should be no form of guard where high-tension wires and telephone or telegraph wires are in close proximity. I take this opportunity of correcting an inaccuracy on page 192 of my paper. The times mentioned for the operation of the Merz-Price and Merz-Hunter systems refer to the times required for the operation of the relays which control the switch-tripping device. The latest types of high-tension switchgear will open the circuit in $1/25$ second after the relay operates. Even with the addition of this time, it is inconceivable that a fallen high-tension wire could reach the ground before becoming "dead" with the Merz-Hunter system, and it is certain that no synchronous plant on the system would have time to fall out of step with that or the Merz-Price system.

Mr. Driver's remarks are outside the scope of the paper, but his reference to foreign practice is nevertheless very interesting. I do not think anybody would erect 10 sq. in. aluminium conductors on a high-tension overhead line, but it has been done on low-tension lines with considerable saving in cost when compared with copper.

Mr. Brazil joins issue with me over the question of line protection by apparatus involving the use of a spark-gap (or an arc gap). The discussion has shown that my views are shared by engineers who have had considerable experience in the operation of overhead high-tension lines in this country, and who have given much thought to this admittedly difficult problem of protection. I refer particularly to Messrs. W. B. Woodhouse, C. D. Taite, P. V. Hunter, and C. Vernier. I am aware that horn arresters have been extensively used with apparent success on low-tension overhead systems for many years, but this result has in my opinion come about in spite of the arresters, and is due to the inherently high factor of safety on these systems. Reference to the test pressures in Appendix XII shows that when dry there is an approximate factor of safety of $15\frac{1}{3}$ on a 3,000-volt insulator and only $5\frac{2}{3}$ on a 20,000-volt insulator; these become 90 and 37, respectively under the spray test. On low-pressure systems the factor is still higher. I think our President, whose Address we both quote, has shown by oscillograph tests that the highest pressure rise which he has found on an alternating-current circuit is not more than 4.4 times the working pressure. This has led me to the conclusion that far more damage is done by high-frequency disturbances

Mr. Weibour.

than by surging at the intended frequency of the supply circuit. The increased pressure accompanying these disturbances is frequently insufficient to cause the horn arrester to discharge, and so it does not meet this difficulty.

Deeply-bought experience in some districts in this country has caused the discarding of horn arresters. When they spark (or arc) over, they are themselves starting fresh high-frequency oscillations—the very thing which it is desirable to avoid. I think it is not unfair to inquire why horn arresters have been so gradually discarded on high-tension lines in the United States and Canada in favour of electrolytic aluminium arresters and other devices. One speaker has pointed out in the discussion that the horn arrester is an objectionable feature of the aluminium arrester. An American investigator has shown that the horn arrester has a time-lag, and that it is possible for a pressure front to pass it before the arrester can act. In concluding my reply to this most interesting contribution from Mr. Brazil, may I also quote our President's dictum that "any arcing or sparking taking place in a circuit is liable to set up oscillations which may give rise to dangerous pressure rises," and mention that porcelain insulator makers are turning their attention to the design of insulators which will withstand these high-frequency effects.

In reply to Mr. Trechmann, some transformer makers now employ the specially-insulated end-turns as their standard practice whether the transformers are for use on overhead lines or not, and therefore the question of extra cost does not arise. As regards regulation, in practice the regulation of a transformer is settled by the maximum short-circuit current which the makers can allow to pass through it. The additional insulation has no effect in practice because the maker purposely makes the regulation worse than would be the case if he were neglecting this question of short-circuit conditions. I am inclined to agree that the number of end-turns to be reinforced would probably be less than 10 per cent as working pressures are increased above 20,000 volts, alternating. At and below that voltage, the 10 per cent arrangement seems to be quite satisfactory.

I have not heard of any trouble from static charges on 20,000-volt lines in this country, or of any resulting trouble with Moschick condensers, which are now being made for working pressures up to 45,000 volts, alternating. The number of condenser tubes to be installed is settled largely by experience after inquiry into the local conditions. It is conceivable that all the fuses might be blown during an exceptional thunderstorm. Where static charges are to be feared on an overhead line it is advisable to make provision for their dissipation. This may be effected—

- (a) By earthing the neutral point of the system.
- (b) By earthing each conductor through an impedance coil or through a high resistance.

I know that Mr. Paton had some unfortunate experiences several years ago with flexible binders and I do not wonder that he is prejudiced against them. I have made close inquiry as to the behaviour of the flexible binder shown in

Fig. 8 and find that over a period of seven years and with experience of several thousand binders, only one binder has stretched and had to be replaced. This occurred at a corner pole. Both with this and with Mr. Paton's semi-rigid binder, experience in fixing and good workmen are essential. In fact much experience is needed throughout in design and erection to obtain a successful high-tension overhead line. The question of abrasion with this flexible binder has also been looked into and there is no evidence of it in one of the most exposed districts in England.

I particularly wish to thank Mr. Wigham for the loan of the Cornwall slides. They have been much appreciated at the Local Section meetings. The artistic design of the sub-station has called forth favourable comment, and it is to be hoped that the design will lead to improvements elsewhere.

As questions have been asked about the use of the "drop-factor" method given on page 181, I give the following notes with examples of its use in the hope that these may make the method quite clear:—

The tables in Appendices III and IV are for single-phase lines, but they can be used for three-phase lines by taking half the three-phase load and calculating as if it were single-phase. For example, assume that 50 kw. are to be supplied at a pressure of 1,000 volts, single-phase or three-phase, at the point of delivery. The power factor is 0.95; the length of line is 2,000 yards; the conductors are No. 1 S.W.G. copper; the periodicity is 60 cycles per second; and the spacing between the conductors is 12 in. Then the two cases are as follows:—

Single phase.—The apparent kilowatts = $50 \div 0.95 = 52.6$; \therefore current = $52,600 \div 1,000 = 52.6$ amperes.

From Appendix III the resistance per 1,000 yards of No. 1 S.W.G. copper wire = 0.69 ohms. \therefore Voltage lost in the resistance = $2 \times 0.694 \times 52.6$, i.e. 73 volts.

Again, from Appendix III the ratio of reactance to resistance with 12-in. spacing at 60 cycles is 0.92. In Appendix IV this ratio comes between 0.9 and 1.0, and at 0.95 power factor is equal to 1.252, so that the total drop in pressure is 73×1.252 , i.e. 91 volts.

The impressed voltage would therefore be $1,000 + 91 = 1,091$ volts.

Three phase.—In this case the apparent kilowatts are one-half of the total apparent kilowatts, i.e. 25.3 ($52.6 \div 2$). The current is $26,300 \div 1,000 = 26.3$ amperes, which is equivalent to the current in a single-phase circuit delivering half the output with the same percentage pressure-drop as occurs in the three-phase circuit. Working this out as in the above single-phase example, we obtain—

Voltage loss in resistance = $2 \times 0.694 \times 26.3 = 36.5$ volts.

Total voltage loss = $36.5 \times 1.252 = 45.5$ volts.

The impressed voltage would therefore be $1,000 + 45.5 = 1,045.5$ volts.

It should be noted that the resistances in Appendix III are given for a temperature of 60°F. , and that the necessary corrections should be made for the resistance at other temperatures. By the above method the size of wire for a given pressure-drop can also readily be found with a little practice.

Mr. Webb.

BIRMINGHAM LOCAL SECTION, 7TH JANUARY, 1914.

Dr. C. C. GARRARD: The principal data at present available on this subject come from America. A study of the papers presented to the American Institute of Electrical Engineers would indicate that the chief difficulty at present over there is the so-called corona loss which limits the transmission voltage. The different conditions which prevail in this country are illustrated by the fact that this subject is not mentioned in Mr. Welbourn's exhaustive paper. We may take it, I presume, that for some time we shall not have in this country to any large extent transmission lines operated at pressures higher than 20,000 volts; I should like, however, the author's opinion on that point. I can emphasize the necessity of galvanizing insulator pins. In a certain instance which came under my notice the insulator pins were not galvanized and were fixed into the insulators by litharge cement. Continual trouble was experienced, due to the insulators cracking, which was finally traced to small quantities of rust forming on the pin. Galvanizing got over the trouble. I should like to ask whether the author finds litharge cement suitable for fixing insulators on their pins. I note that the author recommends cast-iron earth-plates. I have been under the impression that copper earth-plates were better practice, but if cast-iron ones are quite satisfactory they are much to be preferred owing to their cheapness. With regard to the protection of lines against atmospheric disturbances, the author states that even at pressures of 20,000 volts there is no need to make provision for protection against lightning where a cable is "fed" on to an overhead line. This is most important, as the opinion has been put forward that some form of protection is necessary. I should like to know, however, whether the author's statement is confined to paper-insulated cables only, or whether it also applies to any other kind of cable.

I do not agree that horn arresters can only relieve a surge voltage by 20 per cent of its value. If this statement were true, horn arresters would be of no use whatever—a conclusion difficult to reconcile with their large and continued use. It is quite true that they are a somewhat crude method of protection, but on the other hand they are very cheap. If expense is no object a much better system of protection can be installed either by means of Moscicki condensers or aluminium cells. I do not agree that the resistance in series with a horn arrester should limit the current to earth to 10 amperes. The resistance should be about 50 ohms, which on a 6,000-volt three-phase line, with neutral earthed, would give a current of 76 amperes. To deal with such a current a liquid resistance should be installed rather than a carbon rod. Steimetz has also shown that with such a horn-gap and a series resistance—and of course a choking coil—installed at the transmission station a pressure higher than 50 per cent above the normal cannot enter the station. A general condemnation of spark-gaps in connection with arresters is, in my opinion, not permissible. The aluminium lightning arrester, which has been used extensively in America, although originally invented in this country, has a spark-gap. Excellent results are claimed for this arrester, and I believe the claims are justified. The Giles valve, which is made by the manufacturers of the Moscicki condenser,

also employs spark-gaps, and I believe it gives very good results in connection with the protection of machines. As regards the use of condensers for protective purposes, I have no doubt that theoretically they are perfectly correct. Moreover, they have been widely used, especially on the Continent, and experience has shown that they have given satisfactory results where all other systems have failed. In Fig. 12 six condenser elements are apparently shown per phase. In series with each tube is a fuse, which blows, I believe, when a discharge takes place. It would be very interesting if the author would state whether there is any danger of all the fuses blowing during a severe thunderstorm and leaving the power station unprotected. I should also like to refer to the very short times within which it is stated in the paper that certain protective devices remove faults from the line. In the first place I presume the times given are those within which the device begins to operate, as no automatic switch could complete its operation in so short a period. Also I am doubtful whether such a very short period is desirable owing to the heavier duty thereby imposed on the oil switch. It is found that the short-circuit current is very much larger in the first instant than it is, say, one second after the short-circuit comes on. With the continual increase in the size of generating and distributing systems the breaking capacity of the oil switch becomes a limiting feature, and it is therefore important that an instantaneous disconnection of a short-circuit should not be possible.

Mr. F. J. MOFFETT: The present state of the law in regard to wayleaves is an anachronism, and is a very serious handicap to electrical development generally. It is the duty of the Institution to see that in the matter of legislation we in this country should be freed from such disabilities and placed on a level in this respect with other European countries, if not with the United States. I agree with the author that wooden poles properly treated with creosote are the most suitable for all positions except where appearance is a consideration. A few years ago I examined some poles which had been erected over 40 years, and which were being removed to allow of heavier poles being substituted. They were in very good condition, including the part below the ground. In many industrial districts, such as the Black Country, the air is so laden with acid that the life of iron or steel is short unless care is taken to coat it periodically with some preservative such as coal-tar or bituminous paint. Some years ago a process for the construction of poles of reinforced concrete was brought out. Such poles should have a long life, but do not appear to have come into use to any great extent. I should like to hear whether the author has had any experience of them. Since aluminium has been produced with so much smaller a percentage of impurities than was the case a few years ago, it appears to be much less liable to corrosion under most conditions, and is now in this respect as satisfactory as copper. The chief drawback to its use is the difficulty of making a good electrical and mechanical joint. The twisted sleeve joint is simple and fairly satisfactory: the two ends of the cable to be jointed are inserted side by side in a sleeve which is

Mr. Moffett. then given some six complete twists. In my experience of overhead construction I have found that the most effective method of tying in the line wire is first to cover it with a lapping of soft copper tape and then to tie it in with a soft copper binder. I do not agree with the author in his dislike of any form of lightning arrester involving a spark-gap. Several years' use of Wurtz multiple-air-gap arresters on overhead lines has convinced me that they form an efficient protection. These lines were erected in Nigeria, a part of the world where thunderstorms are much more violent and frequent than in this country. No choking coils were used in connection with these arresters, but no damage was ever done to machine windings or switchgear.

Mr. L. F. MOUNTFORT: As I am responsible for a high-tension transmission line in the immediate neighbourhood I naturally welcome this paper very heartily and I feel sure that this subject will become in the future of increasing interest to us in this country. Referring to the comparative costs of overhead line and cable given by the author, I should like to know whether the poles are ordinary single poles or A-poles, as the cost of the line seems to me unnecessarily high. In the Appendix the author gives a table of "drop-factors" for calculating the voltage loss in transformer lines. I should like to suggest that we might have a table that would give us this information directly in terms of the size of wire and would be subject to no greater errors than are involved in the author's table, to which he refers and which are as he remarks, practically negligible. In order to make this clear I put forward the following table, which is one that I have found very useful in transmission-line work. This table shows very clearly

wires, not only on account of its longer life but also on account of its greater conductivity. I am sorry the author has been so severe in his condemnation of spark-gaps. Our 6,000-volt lines are protected with arresters of the "multi-gap" or "low equivalent" type where they enter the sub-station, and choking coils of wrought iron are placed in each line. This apparatus has given no trouble since its installation, and spark-gap arresters are installed in all the sub-stations on the 2,000-volt system. It seems probable that the spark-gap arrester finds its chief usefulness in systems of moderate voltage—6,000 to 10,000. Beyond these pressures the number of gaps required makes the apparatus somewhat cumbersome and it would probably be better to employ the electrolytic or other form of condenser arrester. It is interesting to hear that in the author's experience it is not necessary to install any form of protective device at the point of junction of cables and overhead lines, as this has always hitherto been regarded as advisable in order to protect the cable from atmospheric disturbances. With regard to the method of protecting the apparatus in the station by placing extra insulation on 10 per cent of the windings on the line side of the transformers, there does not appear to be any reason why a fixed percentage of the end turns should be reinforced in this way. This would appear to depend upon the voltage of the supply, as a transformer of comparatively few turns would probably have the impact stress of a surge distributed over most of its windings, while one of many turns would only be stressed through a small percentage of its windings. One objection to this method of protection appears to be that it protects the

Mr. Mountfort.

the small effect which the employment of large sizes of wire has upon the pressure-drop, especially at lower power factors; and the great advantage in this respect of installing at the receiving end of the line apparatus such as synchronous machines capable of taking a leading current.

I am surprised to hear that the author does not believe there is any necessity for placing the aerial earth-wire above the power wires as a protection against lightning. I think that it is decidedly useful in this respect, although I agree that it should be of the same material as the power

station but not the line, and as a punctured insulator generally means a shut-down it would seem advisable in cases where continuity of supply is important to install some form of protection for the line as well.

Mr. B. WELBOURN (*in reply*): Many of the points which have been raised have already been dealt with in my reply to the London discussion, and I would ask members to refer to it. Dr. Garrard referred to the question of the raising of working pressures. As I stated in the paper, my belief is that we are now on the eve of the raising of

Mr. Welbourn.

working pressures above 20,000 volts (alternating current) in this country. This seems inevitable in view of the increasing transmission distances and the larger number of kilowatts to be transmitted. I have had no experience with litharge cement, but I have come across cements which have swelled after a few years' use and have burst the insulators. This is one of my reasons for preferring pins fixed with tarred yarn. The statements about the use of

cable for connecting up a high-tension line applied to paper-insulated cable. It has been proved everywhere that this type of cable is the only one which will withstand high-tension working conditions out-of-doors. I am exceedingly pleased that Mr. Mountfort has given us the table which he has found useful from experience. One of the features of these discussions is that so many useful points have been brought out.

Mr. W. Bourne.

DISCUSSION ON

"ELECTRICITY SUPPLY OF LARGE CITIES."

SCOTTISH LOCAL SECTION, 9TH DECEMBER, 1913.

Mr. F. A. NEWINGTON: I am afraid Dr. Klingenberg's address is rather a difficult one to discuss. The author has taken three cities which he considers typical. I do not know what he means by that—whether typical of the countries they represent or not—but I think that London is the very worst example that could be taken in this country, because electricity supply started in London in the very early days, and the Government allowed London to be divided into a large number of small districts, each to be supplied by one or two undertakings. The object was to prevent such a monopoly as exists in the case of gas. Now we see that it was a great mistake; but at that time it was thought to be the better plan. By dividing up London in that way it has become impossible to have a general supply from a few large centres. The author assumes, or at least suggests, that it might be possible to do away with the whole of the present stations and to build large new central stations, but I do not know how he is going to get over the difficulty of the large capital expenditure that has been incurred, which is, I believe, over £3,000,000 sterling. He says the existing mains would do, but that all the generating plant would have to be scrapped; I suppose that represents a sum of between four and five million pounds. How is interest to be paid on that capital? Towards the end of his address he mentions that the paying-off of this debt has been allowed for, but he does not show how. I think that debt would very much outweigh the benefits of the large new generating stations. Berlin seems to be very fortunate in that respect. It had a very large number of private plants apparently merely supplying electricity to blocks of buildings, and when the larger stations were started I suppose some of the small private stations were shut down, but there was no question of having to buy up these undertakings. In Chicago it seems that the old undertakings were purchased at an outlay of 10 or 15 per cent of the cost of the new works. That is an extremely low price, and the company were very fortunate in being able to buy up the old undertakings so cheaply. I suppose the undertakings had not developed very far at that date. Of the three cities selected for comparison, I think it is a pity that London was chosen. Manchester or Glasgow would

have compared on more equal conditions with Berlin and Chicago. It must be remembered that the London companies are in no way to blame for the existing state of affairs. They were each allotted their small area, and were not allowed to combine, and their life was limited from the very beginning. Dr. Klingenberg's address might be of value 15 or 16 years hence, when the London County Council will be considering the purchase of all the present undertakings.

Mr. Newington.

On page 125 the author recommends the transmission of 10,000 kw. through one cable. With the present Board of Trade regulations that of course could not be done in this country. He also refers to a 20 per cent loss in transmission in the other systems. With continuous-current systems at any rate that is far too high a figure—7 or 8 per cent is much nearer; and I think in a city of reasonable size, that is if the city is not too large for a low-tension supply, the low-tension loss must be less than the high-tension loss with transformation. With the long distances discussed it must of course be high-tension, but the loss will be greater. On page 127 the author mentions a load factor of 50 per cent for power and 50 per cent for traction; 50 per cent seems far too high a load factor for power—it means that the works are operating at their full output for 12 hours a day. A much more likely figure is 20 to 25 per cent. Again, 50 per cent also seems too high for traction. I think 30 per cent would be nearer the mark. These figures will make a considerable difference to the author's calculations. The most important point in a matter of this sort has been left out, namely, the selling price. So far as I can see there is no mention of price per unit sold except on page 131, where the author says the selling price in London is 13 per cent lower and in Berlin about the same percentage higher than the normal value. Does he take Chicago as the normal? If so, London is not doing so badly.

Mr. S. MAYOR: I think there can be no doubt whatever that in large cities the association in the same power station of generating plant for lighting, power, and traction, is the correct policy; the economies to be derived therefrom are well brought out in Dr. Klingenberg's address.

Mr. Mayor.

* Address by Dr. G. Klingenberg (see p. 123, No. 225).

Mr. Mayor. The figures given for the ratio of the stand-by plant to the peak load appear to me to be very high. They surely cannot refer to the whole generating plant, including boiler equipment. Even if merely the generators are included, the figure of 40 per cent seems to be extremely high for stand-by plant; and even 25 per cent seems to be high for large plants unless the individual units are very large. The size of the individual unit must have a bearing on the size of the stand-by plant; if a station with a capacity of 100,000 kw. contains only units of 25,000 kw. capacity it cannot do with less than one set spare, equivalent to 25 per cent; but in smaller stations with smaller units a less margin than 40 per cent should be adequate. I think the whole subject must remind us of the prescience of Dr. Ferranti in his bold conception of the Deptford station; this station unfortunately did not realize the early anticipations, largely because the generating plant of the requisite magnitude was not available. Like Mr. Newington, I miss any direct reference to the selling price, which is, of course, a very important factor in the whole question. I do not know what the selling prices are in Berlin, but I think the prices in Glasgow are lower than in any other city of which I have heard. In my own case, for domestic supply through one meter the average cost for lighting, heating, and other purposes only amounts to between 1½d. and 1½d. per unit. It is perfectly certain that with such a cheap supply the development and use of electricity for all kinds of domestic and industrial purposes must go ahead very rapidly.

Mr. W. L. SPENCE: If the author's basic data are accepted, and I think it is unreasonable to assume that he would found his paper on data which could not be substantiated, points of very great importance are brought out. I refer particularly to the influence of combined load factors in reducing the cost of supply. The load factors given are:—light 18 per cent, power 50 per cent, traction 50 per cent, and it is shown that the combined load factor is not sensibly below that due to power and traction only. This is of very great interest, because it is not our general practice so to combine all three supplies. From the traction point of view alone it may be admitted that the advantages of combination are not great, but in any case a reduction of a few per cent in the traction-supply costs is of no particular value, because electrical energy is a very small proportion of the total operating expenses. The traction output is independent of the costs, so that a reduction in the costs brings no increase in the demand. Above all, nothing should be done to encourage further electric street traction, which I consider an anachronism and should be swept away, root and branch, from our ground-level thoroughfares. The combination of load factors, however, assumes quite another aspect from the broader point of view of increasing the general consumption. Each small economy in production, followed naturally by lower charges, leads to an increased demand for heating, lighting, and power, and tends to that broadening of the basis of supply which will ultimately produce a load factor higher than that which exists at present, even in our imagination. If with the present restricted use of electric lighting the general load factor be not sensibly lowered, there can be no doubt that with the enormously increased use which will follow further improvements in the transformation of electrical energy into light, the load

factor may even be improved by the combination of Mr. Spence lighting with the other classes of supply. The author is therefore to be commended in his advocacy of combined power stations and distribution systems for all classes of supply.

Mr. S. A. SIMON: This address should be of interest to everybody connected with electrical engineering because it affects the spread of the use of electricity. Manufacturers and contractors are as much interested in that as the central-station engineers themselves; in fact, they all have to work hand in hand. It is no good having large stations unless there is a load for them, and it is impossible to obtain a load for the stations unless we are in a position to make our prices such that consumers will be induced to use electricity rather than other forms of power, lighting, and heating. Dr. Klingenberg shows fairly conclusively that even under such bad conditions as those in London it would pay to erect large central stations and to scrap the existing plant; and that after allowing for capital charges there would still be a considerable surplus, which would no doubt be utilized in reducing the price of electricity, and thus enabling a larger number of consumers to utilize this form of energy. I do not quite agree with Mr. Newington that London is not a good example to take. On the contrary, I think some of the conditions in London are not very different from those in other areas with equal population. What applies to a large city would also apply to a large area; for instance, in Scotland one might include in one area Glasgow, Edinburgh, and the surrounding towns, and consider whether the supply of electricity from one, two, or three large stations linked together would not be better than the supply as it is with each municipality, each small town, and each outlying district having its own system. When we consider the whole of the south of Scotland, we are greatly handicapped by the multiplicity of systems and voltages. In Glasgow the city is supplied with continuous current at 250 and 500 volts and three-phase current at 25 cycles; the Clyde Valley Electrical Power Company supply three-phase current at 25 cycles, but at a different voltage from the city supply, whilst the outlying towns have continuous-current supplies with voltages varying from 200 to 250. Further east there are two-phase and three-phase supplies at 50 cycles, and Edinburgh has a continuous-current supply at 230 volts. This multiplicity of systems makes it impossible for manufacturers and contractors to keep the necessary stocks, and it adds to the difficulties of manufacture. This must tell on the prices which the public have to pay for their apparatus, and by increasing the cost and time required for supplying electrical plant must militate against its more general adoption. The question of big stations for the supply of large cities and districts is one of great importance. Any proposal that would conduce to greater uniformity and a cheapening of the cost deserves serious and immediate consideration.

Mr. E. SEDDOX: A consumer is frequently offered a Mr. Seddix supply of energy at a certain price and at a certain load factor, although the latter appears to form an entirely wrong basis for fixing a price, inasmuch as it depends principally on the extent to which the prospective consumer is able to improve the load factor at the generating station. The consumer will sometimes offer a 60 per cent load factor when with a different time of peak a load

factor of 30 per cent would be more profitable to the undertaking, i.e. if the peak of the prospective load coincides with the station peak a higher price per unit would be chargeable with the same load factor than would be the case if the consumer's peak did not coincide with the maximum load at the station. The better practice would be to hand a copy of the station load curve to the consumer with the statement that the lowest possible price would be quoted if he could provide a load which would allow the valleys in the curve to be filled up. The question of scrapping plant is a very important consideration when a high price per kilowatt has been paid and when the period over which the loan is spread has still a considerable time to run. In the present state of the law, plant which has not been paid for cannot be scrapped, for otherwise the balance-sheet of the undertaking would show liabilities against which there were no assets. There is, of course, no reason why modern plant should not be added to an old station leaving the old plant standing until the undertaking can afford to buy it out.

Mr. G. S. HELME: There is a point on page 129 which I think has not been sufficiently emphasized. The author states that the nature of the load in London should be altered; the same remark might be applied to other large towns. In my opinion this alteration should be on the lines of encouraging the consumers to adopt electric heating and cooking. Central-station engineers, though doing more than they did in the past to cater for this kind of load, have still plenty of scope for improvement, in that far too much is left to the manufacturer in the way of reducing the initial cost of apparatus in order to compete with gas and coal. A feeling has been prevalent that central-station engineers have been far too anxious in the past to secure large works as consumers, and this policy often results in prices being cut to such an extent that it is debatable whether current can be generated at the price charged for it.

Mr. J. A. ROBERTSON: The question which interests us most is the London problem. I suppose that if we had to start afresh nobody would dream of putting down 64 small stations to supply the London area. It is remarkable, however, that in looking into the tables of comparative costs, how well the London stations come out when we take into consideration the cost of coal freight and the absence of proper condensing facilities. I make it out that while the total works costs for London amount to 120d., for Berlin after deducting the amount of municipal participation they are 60½d., and for Chicago 0·34d. Part of the higher cost in London is accounted for by rent, rates, and taxes, over which the undertakings have no control, so that the difference is not so great as it appears at first sight. I agree with Mr. Newington, however, that London should not be taken as an example of the best we can do in this country. Many of the London undertakings represent pioneer work and are burdened with obsolete plant, and handicapped by conditions which do not exist either in Berlin or Chicago. One reason why these stations have not been scrapped in favour of several large central stations is the purchase conditions of the 1888 Act and the fact that the companies owning these undertakings can have very little idea of the terms on which their undertakings may be purchased when the local authorities come to exercise their statutory powers.

If Dr. Klingenberg had taken one or two large provincial stations such as those at Manchester or Birmingham, he would find that the relative costs of generation and the selling price compare very favourably indeed with Berlin or Chicago. The figures given for Chicago show the immense importance of a traction load combined with a power and lighting load, and there is no doubt, I think, that the proper thing to do is to combine all the classes of supply in one station so as to obtain the highest possible diversity factor. Dr. Klingenberg compares the relative costs of a station near the centre of supply with a distant station. The idea of placing large generating stations in the coalfields appears a very attractive proposition. It must be remembered, however, that the modern power station depends on steam turbines for cheap generation, and to work turbines efficiently an ample supply of condensing water is necessary. This supply will not always be available in the coalfield districts, so that the sites of the large power stations of the future must be a compromise; they must be placed where coal freight is not excessive and where water is abundant.

I was surprised to learn that the Berlin municipality extracted so large a sum as 10 per cent of the gross income of the supply company as the price of the concession, in addition to participating in the profits over a certain sum. We hear a good deal about the vicious practice of taking profits from supply undertakings in this country in aid of the rates, but I do not think that any municipality in this country would dream of taking 10 per cent of the whole income in aid of the city treasury. This diversion of revenue from the electricity undertaking, which amounts to more than the coal bill in the case of the Berlin undertaking, is really a tax on consumers of electrical energy, and I do not think it is fair or reasonable for the electric supply industry to be burdened with such a charge. In considering the London problem we have to accept the fact that these 64 undertakings are established, and while it is impossible to scrap them at once, much can be done by combining the larger undertakings and gradually changing the smaller stations into sub-stations. The whole question is at present being considered by the County Council with the aid of expert advice, and it is probable that we shall have a concrete proposal to discuss at an early date. It will be found in many cases that existing stations can be extended economically and ultimately linked up with one or two large power stations which will represent the most modern ideas in design and equipment. Any conclusions based on the number of units sold per head of population may be somewhat misleading. We have heard about the extensive use of electricity in Chicago, but if the amount of the traction load in Chicago is deducted and the remainder is divided by the population it will be found that the number of units sold per head for power and lighting is 110. In London the corresponding figure is 70 units, but in Manchester it is 99, while in Greenock the figure is 136 units per head, and in several English towns it is well over 100. I mention these figures to show that the position in this country is not so bad by comparison as it appears on the surface.

Mr. W. W. LACKIE: I agree with what Mr. Newington said: the London undertakings commenced their supply in 1882, and Berlin and Chicago in 1888 and 1907; so that the two cases are not really comparable. The mains in

Mr. Robertson

Mr. Lackie

Mr. Lackie. London, which could still be used, represent £13,000,000, whilst the capital expended in London on electrical undertakings is £27,000,000. I believe the load factors mentioned will be obtained when there is a universal supply of electrical energy. Only a few years ago a Glasgow firm generated as many units as the Corporation Electricity department did, but at a 60 per cent load factor. I believe that the tramway load in Glasgow has only a 36 per cent load factor, but in Chicago the combined load factor is 41 per cent. Mr. Mavor raises the question of spare plant. I think the author merely mentioned that there should be one unit spare, i.e. with four 10,000-kw. sets there should at least be one spare. Dr. Klingenberg refers on page 126 to the cost, and gives a formula for it, but I should not like to go to a consumer and tell him that that is how the costs are made up. Like Mr. Seddon, I should prefer to show the load curve and tell the consumer that I want him to improve that curve, and a price can then be arranged. Mr. Simon suggested large stations of uniform voltage. When the pressure was raised in Glasgow to 250 volts we were told that the price of lamps would be doubled if everybody adopted a uniform pressure. Mr. Seddon referred to load factor: we have a case where there are two mills, one running all day and the other all night; the load factor of each mill is 30 per cent, but we shall have a 60 per cent load factor on the station. Mr. Helme says we are not catering for new sources of supply. I think we are, and I would refer him to the recent Electrical Exhibition in Glasgow, which was most successful. The erection of a station near a coal-mine raises a very debatable point; for if a station is placed near a coal-mine it is tied to that one pit, and if a coal strike takes place at that pit where can coal be obtained? It is better to be so situated that coal can be obtained from any pit. In Chicago, three independent stations are being built on one site, and it is believed that a 240,000-kw. station is the largest that should be built. I have seen the site and the plans for these three stations, and I notice that it is considered the correct policy to build the stations inside the city and bring the coal in. I do not see how the nature of the consumption in London is to be altered. We have got to take the present conditions.

There is one other point. Nowhere throughout the paper has Dr. Klingenberg referred to the effect of the diversity factor, which is a most important factor in the sale of electrical energy. The number of units sold per head of population in Greenock, which holds the record in this country, is 135, double what it is in Glasgow. It shows the nature of the load, which is largely power. A sum of £500,000 was spent in Chicago last year in installing battery sub-stations. It is believed there that everything possible must be done to ensure reliability of supply, and the lighting of the whole of the centre of the city can be supplied from storage batteries if necessary. This means an increase of £2 per kilowatt in the cost of the plant. It is most difficult to make comparisons between one town and another, and while Dr. Klingenberg's address is of great interest and value it is not one which can be readily discussed as a technical subject.

Dr. G. KLINGENBERG (*in reply, communicated*): Mr. Newington's remarks as to the difficulty of overcoming the large capital expenditure on the existing stations and the repayment of this debt might be justified if I had assumed

that all the existing stations were to be replaced at one time. Dr. However, from the information which I possessed I felt convinced of the practical impossibility of such a proceeding, and I therefore confined myself to a programme whereby the reconstruction could be carried out step by step without interfering with the liabilities due to the existing capital. The surplus arrived at in Table VI shows that the first step in the programme which I adopted promises to be in the right direction, because this surplus was obtained after I had allowed 8 and 10 per cent on the new, and 8 per cent on the present capital of the 25 old stations (see items 14 and 16, Table VI). The last percentage for paying off is even higher than the average total percentage (7.85 per cent according to item 30, Table III) earned under operation during the year 1910-11.

Criticism has been raised with regard to the load curves for power and traction shown in Fig. 1, which were based on a load factor of 50 per cent. Apparently it is overlooked that these diagrams refer only to large power stations, and that the load factors therefore represent values obtainable under the best conditions, i.e. with the highest diversity effect for each individual class of consumption given in Fig. 1. In regard to power especially it must further be taken into account that in large cities the load on Sundays falls almost to zero, so that the yearly load factor (Fig. 1 refers to daily load diagrams, excluding Sundays) for power will be smaller approximately in the ratio of 6 to 7. A similar, though not so great a reduction, will apply to the load factor for light and traction if taken over the year, depending on the special living conditions in the towns on Sundays.

It should further be noted that the load factors in Fig. 1, contrary to English custom (see the statistics published by the *Electrical Times*), are based on the number of kilowatt-hours generated; in order, therefore, to bring these values into line with the load factors given in the *Electrical Times*, they have to be multiplied by the efficiency of the transmission. Taking this into account, it will be found that the actual load factors (item 20, Table III) compare very well with the values taken from Fig. 4 (which is based on Fig. 1), and seem therefore to confirm the correctness of the load curves in Fig. 1.

It has been pointed out that I have made no reference to the selling price of the current. This remark is only correct in so far as I have not discussed the individual selling costs for the different classes of consumers, which I considered to be outside the scope of my address; all that appeared to me to be important in connection with the subject was the average selling price of electrical energy in the case of large companies. This point has been fully dealt with, both as regards the actual prices obtained (see Fig. 5 and item 31, Table III) and the desirable or "normal" prices as I have called them. From my explanation of "normal selling price," it will be seen that I do not consider the results of the various towns to be directly comparable with one another, but that I attribute to each town a scale of "normal selling prices" representing, generally speaking, the lowest prices at which a prosperous development can still be expected under the prevailing conditions. These curves and formulae therefore offer the safest guide in predetermining the price for current as closely as possible, and beyond this the method used opens out a new prospect with regard to the question

gen-of tariffs. In this connection I come to a point raised by Mr. E. Seddon, viz. that instead of offering a customer a price based on his load factor, the price should be fixed according to the improvement of the load factor at the generating station. This I consider to be fully correct, except that as a result of my researches in this respect I have to go a step further than Mr. Seddon, by maintaining that the selling price to each customer should be based upon his utilization of the whole undertaking, i.e. on his improvement of the utility factor of the entire system, instead of on the load factor of the central station only. It is of course practically impossible to determine this effect for each individual customer. My address, however, contained a practical proposal towards the above ideal way of fixing the tariff. I showed that in large cities the load curves of special classes of consumers could be considered as constant, no matter what the load factor of a single consumer in such a class might be; or, to put it differently, that in large cities for certain classes of load the diversity had reached its maximum. Once this has been admitted, all that is necessary for the ideal tariff is to find the diversity amongst the classes of demand for any combination. This I have done in Fig. 4 (see also page 148 in my reply to the London discussion) for the three classes—light, power, and traction. My address therefore involves the conclusion that a tariff based only on the maximum of the individual consumers is wrong for large cities.

By "Nature of consumption for London" (page 120), to which Mr. Lackie refers, is meant the combination of power, light, and traction, which can be altered, for instance in London, if more traction load is included in the general supply.

Several engineers have remarked that the data I have given for practical examples were not well chosen. I admit this to the extent that it would have been to some

extent advantageous if I had discussed the latest data for 1912-13, but unfortunately I was not able to secure the same complete, authenticated information simultaneously in all three cases for years later than those which I have taken. In other respects I must uphold what I said in the address, that I consider the plants of Berlin, Chicago, and London as good examples as I could find with regard to the subject of my address, and I believe that a comparison of their historical development with the capital expended on and the working results obtained from them will confirm this contention.

In reply to the remark that I ought rather to have taken another English city instead of London in order to show better working results, I can only say that my address is misunderstood, since it was not intended to compare towns on the basis of maximum records for working costs. If this had been the case very probably none of the examples that I have taken would have appeared in the address; and I can only say that if any qualifying conclusions are drawn from my address regarding the engineering of the average London supply (see especially Fig. 5), these could not be otherwise than highly complimentary to the London engineers, who, notwithstanding the extremely unfavourable conditions, have been able to manage the supply in such a way that they lag neither in regard to reliability of supply nor in price of current behind the works of similar large cities which were placed in a much better initial position.

I regret that owing to an oversight I omitted to mention in the copy of my address printed in the *Journal* the co-operation of my assistant, Mr. R. Tröger, which I acknowledged when reading my address before the Institution. I take this opportunity of expressing my best thanks to Mr. Tröger for the valuable assistance which he has rendered me.

Dr. Klingenberg

NOTES ON INTERNATIONAL STANDARDIZATION OF ELECTRICAL MACHINERY.

By A. R. EVEREST, Member.

(Introductory notes to a discussion before the BIRMINGHAM LOCAL SECTION, 10th December, 1913.)

In all engineering work, in order to produce satisfactory results, it is necessary that there should be a knowledge of the behaviour of materials under different degrees of duty, and that the parts should be so proportioned that the working duty may bear a known relation to the safe limits. In other words there must be a known "safety factor." In mechanical engineering many decades of practical experience, together with persistent research work, have placed at the engineer's disposal the information needed to determine on the one hand what safety factor is proper for the duty in question, and on the other hand what proportions are needed to give the required safety factor.

In the design of electrical machinery similar information is necessary; but due to the rapid development of this branch of engineering, such information has not been in the same way available.

One of the principal tasks assumed by the International Electrotechnical Commission has been to study this subject through the various National Committees in order that all available experience may be brought to bear in establishing the necessary reference data. The information thus collected and discussed internationally at the meetings of the Commission in Paris, Zurich, and finally Berlin, has now been reduced to a form in which it becomes available for practical purposes, and various countries are now engaged in remodelling their National Standardization Rules in accordance with the new I.E.C. standards so far as these have been established.

In order properly to discuss the work of the International Electrotechnical Commission it is necessary to distinguish clearly between an "international standard of quality" and an "international rating" for machines.

The rating of a machine is the output for which it is sold and which is marked on its name-plate (rating plate). This output is the "rated output" of the machine.

(a) *I.E.C. Standard of Quality.*—If the rated output of a machine is such that when working under the particular cooling conditions for which it is designed the machine keeps within the I.E.C. limits of temperature, this machine, for its particular application, conforms to the I.E.C. standard of quality. This standard is particularly valuable for important individual and special applications. Various machines in this class from different sources would still not be directly comparable, since they would not have an equal temperature rise if primarily intended for different conditions.

(b) *I.E.C. Rating.*—If the rated output of the machine is such that when working under the I.E.C. standard conditions of cooling the machine keeps within I.E.C. limits of temperature the rating of this machine is I.E.C. rating. Thus the I.E.C. rating establishes temperature rise as well as maximum temperature. All machines with I.E.C.

rating would be directly comparable amongst themselves since they would all have the same temperature rise at their rated output.

The Rules adopted at the recent I.E.C. meeting in Berlin establish the I.E.C. standard of quality (as regards temperature) for electrical machinery. Agreement was not reached upon the further question of I.E.C. rating, due to differences of opinion regarding the value for the cooling-air temperature. Before referring further to this feature it may be well briefly to review that part of the work which has been completed by the I.E.C.

These Rules are the outcome of deliberations by the various National Committees and at the meetings of the Special Committee on Rating held in Paris and Zurich, and in Berlin prior to the Plenary Meeting.

The Rules so far adopted are based on considerations of the highest safe temperatures for various insulating materials, the joint effect of time and temperature, also the probable difference between observable temperature and maximum internal temperature. From these considerations an international agreement was reached regarding the permissible limits of temperature for various insulating materials employed in modern electrical machinery. In connection with these permissible temperature limits, rules are provided regarding the proper determination of the temperature of the cooling air, a knowledge of which is necessary to ascertain the temperature rise which must not be exceeded at the rated load of the machine.

Finally, rules are provided dealing with the differences which may exist between the temperature rise on test and under service conditions due to variations in the cooling temperature and the barometric conditions. Thus the I.E.C. standard of quality has now been established as regards temperature, and therefore life, for any machine working under the conditions for which it is sold.

METHOD BY WHICH TEMPERATURE IS TO BE OBSERVED.

While the hottest internal temperature at any point determines the life of the insulation affected, the I.E.C. does not consider it feasible to make this the subject of ordinary commercial investigation. Information obtained from laboratory investigations with exploring coils and thermo-couples built into specially prepared machines appears to justify the conclusion that for modern machines wound for not more than 4,000 volts, or for transformer coils for not more than 10,000 volts, the hottest internal spot will not exceed the temperature observed by ordinary methods by more than 10 degrees Centigrade. Accordingly the limiting observable temperatures permitted, which are shown in the Table below, apply to measurements by the rise of resistance of the winding (wherever practicable), together with the use of thermometers, the highest reading found being always con-

sidered. Electrical thermometers and thermo-couples applied to any accessible part of a completed machine are classed with thermometers.

THE QUESTION OF OVERLOADS.

A great deal of confusion exists between different countries at present concerning the relation between the so-called "full load" rating of a machine and the highest load it is actually expected to carry. Further, the various overloads are rated for different lengths of time, and in some cases are not allowed at all when the machine has been heated up by its ordinary "full load."

The I.E.C. has decided that any machine intended for continuous service should be ordered, designed, and rated for the highest load it is expected to carry, and that it should be capable of carrying this rated load continuously without exceeding the temperature limits of the Table. No overloads are permissible beyond this rated load.

In the case of a machine subject to peak loads in excess of the ordinary load, if the peak endures for more than a short time it must be included in the rating. But if the peak load is to be endured for brief periods only, the rating must be sufficiently above the ordinary load to give a continuous thermal capacity equivalent to that required on the brief peak loads without exceeding the permissible temperature limits.

INTERMITTENT SERVICE.

A machine for intermittent service may for the purpose of test have either a continuous rating which is thermally equivalent, or a "short time" rating which when starting cold and running at a rated load for a specified time shall not at the end of that time attain temperatures in excess of those shown in the Table.

PERMISSIBLE LIMITS OF OBSERVABLE TEMPERATURE.

Upon these considerations the I.E.C. decided to standardize limiting values for temperature which should apply to "observable temperatures" measured by the means and methods specified, and which should be set with due allowance for such excess internal temperatures above those "observable" as would be associated with the approved methods of test. The temperatures were to be such as might be endured continuously without prejudice to a reasonably long life, but there were to be limits which must not be exceeded. Accordingly values have been standardized as shown in the following Table:—

TABLE.

Limits of Observable Temperature adopted by the International Electrotechnical Commission, September, 1913.

	C.
Non-impregnated cotton	80°
Impregnated cotton or paper (general)	90°
" single layer field coils stationary or moving	95°
" stationary coils solidly impregnated throughout	95°
" rotor and stator windings having the slot portion solidly impregnated or moulded	95°

	C.
Enamelled wire (without cotton)	105°
Mica, micaite, asbestos (general)	115°
" single layer field coils stationary or moving	120°
" stationary coils solidly impregnated or moulded	120°
Windings permanently short-circuited—	
Insulated	100°
Non-insulated	110°
Commutators, slip-rings	90°
Bearings	80°

NOTE: When the insulation is composed of several different insulating materials the lowest of the temperatures corresponding to the various insulations employed must be taken as the temperature limit. The insulation even when forming a support is always considered as part of the winding. (Material employed in small quantity in the construction and not relied upon continuously as a support for the insulating material is not regarded as part of the insulation under this rule.)

STATEMENT OF COOLING-AIR TEMPERATURE.

Permissible limits of temperature are useless to the designer except in conjunction with information regarding the cooling temperature, since the difference between these two values is the "temperature rise" which the machine may create when carrying its rated load. Hitherto in the I.E.C. proceedings, as well as in the various National Rules, the value mentioned as cooling-air temperature has been the "ordinary" or average value. Obviously such value cannot be used directly in connection with a table of limiting temperatures "which must never be exceeded."

The corresponding value of the air temperature employed must be the highest which is likely to occur. The British and United States Committees agreed in recommending that in future 40° C. should be taken as the reference air temperature, instead of 25° C. as hitherto indicated in the National Rules. (Unfortunately some confusion arose because the reason for this sudden increase from 25° C. to 40° C. on the part of the British and United States Committees was not explicitly given.)

The I.E.C. Rules now require that the maximum and not the average temperature of the cooling air shall be stated, but agreement was not reached regarding an International Standard reference air temperature. This will be referred to again under "I.E.C. Rating."

CORRECTION FOR ROOM TEMPERATURE DURING TEST.

Extended investigations made by the United States National Committee show that the variation in temperature rise with a given load when tested with cooling air at different temperatures is a small and uncertain quantity, sometimes positive, sometimes negative, according to the characteristics of the particular machine. The I.E.C. decided that no correction shall be made in practice for such difference between the conditions of test and of final service.

CORRECTIONS FOR DIFFERENCE OF ALTITUDE.

No correction is to be made for variation in the cooling properties of the air at a given temperature at altitudes

not exceeding 1,000 metres. For higher altitudes it is recognized that a correction is necessary, but the I.E.C. is not yet in a position to furnish an official correction factor.

"I.E.C. RATING" FOR MACHINES.

Although the I.E.C. states that "wherever possible the temperature of the cooling air should be stated and the machine constructed for this cooling condition," it is also proposed to establish a value which shall be taken as the maximum temperature of the cooling air when no specific information is available. Probably more than 90 per cent of all the machines sold come under this class, and the establishment of an international reference for air temperature in connection with the Table of limiting temperatures already provided would at once fix the temperature rise permissible at the rated load, and in connection with the rulings given regarding overload would completely establish the capacity of any machine sold with "I.E.C. rating."

With such uniform rating adopted, a buyer of standard machines could compare, without misunderstanding or possibility of mistake, tenders received from various makers even from different countries. He would know that all the machines offered would carry their rated loads continuously with the same temperature rise (and also with uniformity in other characteristics such as commutation, as far as these might be defined by the I.E.C. Rules).

It is evidently desirable that the I.E.C. rating shall also be the domestic standard rating of the same machines in the countries in which they are produced. The

reference air temperature must then be set at such a value as shall not be exceeded by the hottest conditions likely to occur in service at any time of the year in any temperate climate.

At Berlin a majority of the delegates, including those from Great Britain and the United States, desired to fix this reference temperature at 40° C., but a minority desired 35° C.

Examination of the meteorological records for various temperate countries, including Great Britain, Germany, and the temperate part of the United States, shows that 35° C. is not sufficiently high to cover even the highest outdoor shade-temperatures which are occasionally recorded, so that with a temperature rise based on the 35° assumption the limiting temperatures of the I.E.C. Table would certainly be exceeded at times. But such is contrary to the express conditions under which the limiting temperatures were adopted by the I.E.C.

In order to justify a *nominal* "maximum" temperature for cooling air which would exclude the highest peaks occasionally occurring, it would be necessary to reduce all the values shown in the Table of permissible limiting temperatures by a margin sufficient to allow for such occasional peaks. This proposition was suggested at Berlin but was not accepted by those desiring the lower reference temperature. Finally, this entire question was referred back to the various National Committees, and it is to be hoped that an early settlement will be reached, as upon this question hangs in reality the whole problem of international standardization in the rating of electrical machinery.

DISCUSSION.

Mr. Peck.

Mr. J. S. PECK: Probably there is no one who will question the desirability of having international standards for the rating of electrical machinery. The standard rules should prove of special benefit to British manufacturers on account of the fact that the German "Normalien" are the standards most generally recognized in the majority of countries to which we export; and since British standards have in general been higher than the German, the British manufacturer has been at a disadvantage when tendering his standard machines against those of Continental manufacture. Continental engineers were probably the first to recognize the desirability of permitting a much higher temperature rise on machines insulated with fireproof materials than on those insulated with treated or untreated fibrous materials. American engineers are now advocating very high temperatures on machines such as turbo-generators where fireproof material is used, and apparently the results of machines in commercial operation justify this practice. It would appear that at last the various nations have practically agreed on the absolute temperatures at which different classes of insulating material can be operated. One point in the proposed rules seems likely to cause considerable misunderstanding. This is the substitution of maximum rating for normal rating with overload. The trouble is, however, chiefly a mental one, for the same factors as formerly will have to be taken into consideration, and the customer must place before the manufacturer the conditions under which the apparatus will be required

to operate in the same way that he does at present. I think special attention should be drawn to the note at the bottom of the table on page 245 giving the limits of observable temperature. Fireproof material such as mica cannot be applied for armature wrappings except with a backing of thin cloth or paper; yet this paper or cloth may be completely carbonized and disintegrated without affecting the insulation strength of the machine; and in such cases it comes under the class in which the highest temperatures are allowed.

Mr. W. J. LARKE: It is of the utmost importance in the interests of the development of the electrical industry throughout the world, as well as of foreign business in the countries which do not produce their own electrical machinery and apparatus, that an international agreement should be arrived at in connection with standardization. As Mr. Peck has stated, in the latter countries we have for some considerable time been at a serious disadvantage compared with our German competitors, due to our adoption of a more conservative basis of rating. But the work of the Commission will prove abortive unless each country represented on it takes the requisite steps to ensure that the recognized authorities controlling the standards of the industry in that country co-operate with the Commission, by changing where necessary the recognized standards of the country to those formulated by the Commission to which their representatives have subscribed. For the United Kingdom this authority will presumably be the Engineering Standards Committee.

It is interesting to note that in America the Institute of Electrical Engineers has already drafted a comprehensive series of rules in which has been incorporated the standards formulated by the Commission so far as these have been established by international agreement. It is unfortunate that the Commission were unable to reach an agreement on what has been termed the "ambient temperature," or temperature of the surrounding air, and Mr. Everest rightly points out that on this question rests the whole problem of international standardization in the rating of electrical machinery. There is no doubt that the attitude of the British and American delegates is correct in supporting such a limit for the ambient temperature as will ensure, under the conditions of climate considered, that the maximum limits of temperature mentioned in the table given by Mr. Everest—the figures in which have been adopted by the Commission—are never exceeded during any period of the working time; and this is the only logical attitude in view of the fact that the limits mentioned are the maxima. As for temperate climates, the limits of ambient temperature should be equal to the maximum recorded during any season of the year, which is given as 40° C. It is to be hoped that at the next meeting of the Commission this limit will be agreed upon, the arguments in its favour being irrefutable. In connection with the table of limits of maximum temperature for various materials, recognition should be given to the extremely valuable pioneer work carried out by a Committee under the chairmanship of Dr. Glazebrook in 1905. It was undoubtedly those important and comprehensive investigations which rendered the compilation of the table now under consideration possible. Reference has been made to what in America is described as the "hot-spot" of machines and apparatus, but it seems both unnecessary and undesirable to take this into consideration in ordinary commercial practice, particularly as the Commission has definitely stated that the difference in temperature between the "hot-spot" and the temperature of those parts of machines or apparatus which are readily observable, has already been taken into account in determining the limits of temperature which the Commission has adopted for the various materials. This difference can obviously only be determined by investigation under research conditions, and it is far preferable that the standards which are to govern the commercial development of the industry should be formulated in such a manner that the tests for determining compliance with such standards may be readily applied under ordinary manufacturing conditions.

With regard to the question of rating, which, as has been already stated, is dependent on the ambient temperature, if 40° C. is adopted for temperate zones, there will arise the difficulty of the rating of machines exported to tropical zones. It must be borne in mind that standards of the character it is proposed to set up apply equally to small machines as to large machines, and whereas large machines are almost invariably specially designed and built for the conditions under which they are required to work, and therefore questions of the ambient temperature or any other local conditions affecting the design can be readily allowed for, in the case of small machines manufactured in quantities this is not possible without following the same procedure as that applied in the case of large machines. Thus a difficulty arises as to the rating of these

small machines which it is desired to deliver from stock for shipment to tropical zones. It seems evident that in every case the ambient temperature of the locality in which the machines are to be used must be taken into consideration, and the machines re-rated accordingly by the manufacturer supplying them, as obviously the user is quite unable to assume the responsibility of re-rating these machines to suit his local conditions if they were supplied on a basis of rating determined by the ambient temperature for temperate zones. With regard to the suggestion that motors should be rated in kilowatts instead of horse-power, this is an innovation for which there seems no reasonable grounds, and one that will be fraught with the greatest possible difficulty and inconvenience. From what may be claimed a considerable experience and acquaintance with users of electrical machinery, it may be definitely stated that the difficulties of introducing electric driving, particularly to small users, will be considerably enhanced by following this procedure. All prospective users of electric power think in horse-power, and any prime-mover which it is proposed to supersede by an electric motor is invariably rated in horse-power unless it is a manually-operated device. To introduce needlessly a new unit which would require explanation and discussion with the prospective user, and without obtaining any but an academic advantage, would introduce a modification which if in itself of minor importance (since two sets of ratings in catalogues, etc., could be printed) is at the same time detrimental to the best interests of the industry.

Mr. C. LE MAISTRE: The electrical industry is to be congratulated upon the public-spirited and cordial way in which the manufacturers are co-operating in the establishment of satisfactory standards for this country. The close co-operation recently established between the American Standards Committee and the British Engineering Standards Committee is certain to be of mutual advantage to both countries and will ensure the adoption, by English-speaking people, of standards of the highest quality. The general public now have confidence in the freedom from breakdown of English electrical machinery, and whatever standards are adopted in this country must be of such a nature as not in any way to encroach on this confidence. As regards the international aspect of the question, I feel quite confident of the ultimate success of this work, for our continental friends have, in just the same manner as the English and American engineers, placed their very best men at the disposal of the Commission for the working out of these problems, and Mr. Everest will bear me out when I say that the Delegates to the Special Committee, both at Zurich and at Berlin, were all actuated by the highest motives. Although it is only a small part of the work to be accomplished, the recommendations which the Commission has already made in regard to the rating of machinery will appeal to both maker and user alike as being of real utility. Again, the standards adopted by the Commission must be of a really international character if they are to command the respect of the world; and the interests of those countries which are either hotter or colder than temperate climates must carefully be borne in mind. It is true, of course, that temperate climates contain the very large majority of users of electrical machinery. As General Secretary of the Commission, even were I competent to do so, I am debarred from entering into any detailed criticism

Mr. Le
Malistre

of Mr. Everest's notes, but I may mention that the Central Office of the Commission in London will do everything in its power to help forward international agreement on this important subject. To be able equitably to compare different tenders must be of such material advantage to the progress of international trade in electrical machinery and the difficulties of arriving at a satisfactory basis of comparison are by no means insurmountable with so much good-will at the disposal of the Commission—that it is well worth striving for.

Dr. Kapp.

Dr. G. KAPP: The decision of the International Electro-technical Commission not to establish any rules for the correction to be made for ambient temperature or altitude is justified by the contradictory experiences brought forward by several delegates. As the influence of the density of the cooling medium is exceedingly complex, this may account for the discrepancies between the results obtained by different observers. On a superficial consideration of the problem it would naturally be supposed that the cooling effect of the air would be reduced if its density were lowered, either by reason of a higher initial temperature or a higher altitude. It should be remembered, however, that it is not the volume but the weight of air and the velocity at which it passes along the surfaces that determines the number of calories which it can carry away. As it is quite conceivable that owing to the special configuration of the body or the supply of a definite power in working a ventilator there would be no great reduction in weight of the air passing the body in unit time whilst the velocity is increased, no material difference in the temperature rise would be observed whatever the density of the air (within reasonable limits). As regards the question of a standard ambient temperature, I would point out that the adoption of 40°C., as advocated by the British and American members of the Commission, is not unreasonable, when the necessity of providing a certain factor of safety is considered. The yield point in the stress of a bar of steel can be found with a fair degree of accuracy, but the thermal yield point of any particular type of insulating material is not so accurately known. That such a point exists has been shown by Mr. Rayner, and later by Dr. Steinmetz and the brilliant group of American engineers working on this subject; and although it may not be known to 1 degree with absolute certainty, all experts agree that a decrease or increase of 5 degrees makes all the difference between a long and a short life of the insulation. The Commission has agreed on certain upper limits of "observable" temperature; these values are probably not very far from the yield points and for this reason they must not be overstepped. It is therefore a wise precaution to agree on an ambient temperature sufficiently high to ensure that these maximum temperatures shall not be exceeded even on a hot summer's day. The cost of a machine is only slightly increased by adopting the ambient temperature of 40°C. as a starting-point to arrive at the permissible rise, whilst the extra security against breakdown and the consequent possibility of reducing the amount of spare plant are certainly in the interest of the user. Nowadays, when electricity has become so important a factor in all industries, electrical engineers must not run any avoidable risk, and even if the provision of a generous factor of safety should increase the cost of a machine by a few per cent, it is eventually in the interest of the user

to pay a little more for a reliable article than a little less for a cheaper and unreliable article. This is the policy followed by the best English and American practice, and in the interests of electrical engineering we can wish for nothing better than that it should become the policy of electrical engineers of all countries.

Dr. M. KAHN: AS Mr. Everest has pointed out, two questions have arisen in connection with the standardization of temperatures of electrical machinery:—(1) "Maximum temperature limits" (these have been agreed upon by the International Standardization Committee and need not be discussed); (2) "temperature rise" (no agreement has been reached upon this question). Some points which have to be considered in settling the temperature rise that can be allowed are as follows:—The electric motor is now practically without competition for the ordinary commercial drive, so that the question of rating can be settled by representatives of the electrical industry without regard to competing methods. There are of course a few cases like the driving of cotton mills or large rolling mills, or heavy traction, where the electric motor is still in competition with other means of driving, but such cases may be neglected, as the considerations which will finally determine the issues are other than those under discussion to-night. There cannot be any doubt that a conservative rating is to the best advantage of all concerned. Above all, the user of electrical machinery requires reliability, and the manufacturer of electrical machinery has the greatest interest in supplying a thoroughly reliable article. If a conservative rating is universally adopted, the only consequence will be that the price of electrical machinery will be kept at a certain standard; this can only be to the advantage of everybody concerned, including the buyer, as the latter receives a satisfactory article which will ultimately cost him in upkeep and repairs less than a machine that is rated too high.

There is no doubt that machines sometimes have to run in rooms where the temperature of the surrounding atmosphere is 40°C. This condition of course does not often prevail. Machines will in the majority of cases run where the temperature is about 25°C., and the difference of 15°C. can be regarded as a factor of safety. Factors of safety are always adopted in engineering, and I do not see any reason why a factor of safety should not also be used in connection with rating. The maximum load that a generator has to carry is usually known, namely, the maximum load the driving prime-mover can give; in the case of motors, however, the maximum load more often than not is unknown both to the user of the motor and to the manufacturer. Moreover, motors are often overloaded—for instance, by adding new plant to that already driven by the motor, or, even without any such alteration, due to increased friction in the bearings of the driven machinery and the line shafting. It may of course be said that this should be allowed for when ordering a machine; but I am quite certain that it would be impossible to persuade a customer who has been accustomed to buy a 20-h.p. motor and obtain a certain power from it whilst also having something in hand for contingencies, that in future he will have to specify a maximum load with a certain margin above the normal load. In other words, if he wants a 20-h.p. motor he would have to buy a 25-h.p. motor. All this can be obviated if the rating of the motor

is settled in such a way that in case the rating allowed is exceeded by a reasonable limit no harm will be done to the machinery installed. It may of course be said that it is unnecessary to settle temperature rise at all, and that the temperature of the surrounding atmosphere can be stated in every case. This has as a matter of fact been done to a certain extent by the decision temporarily arrived at at the latest meeting of the International Standards Committee, but this solution is most unsatisfactory as it is essential for the manufacturer to standardize.

Mr. C. T. STEIN: I should like to congratulate Dr. Kapp on his lucid explanation of the reason why the temperature rise of electrical machinery is unaffected by the value of the initial air temperature. At the same time I should like to point out that his theory does not make any allowance for the actual increase in the value of the loss in such machines at higher initial air temperatures, owing to the increase in the resistance of the windings. With regard to the method by which temperatures of electrical apparatus are to be measured, I think that it is very much to be desired that some definite rule be fixed, standardizing the exact method of measuring the temperature rise of various parts of such machines. Unless this is done the manufacturer who bases his guarantees on a temperature rise by the "increase in resistance" method will be handicapped in comparison with a manufacturer who bases his guarantees on the temperature rise by thermometer. It is to be hoped that in this standardization the tendency will be towards the use of thermometers rather than of the "increase in resistance" method for determining the temperature rise, as although the measurement of temperature rise can usually be more accurately determined by the resistance method, nevertheless, thermometric readings are invariably preferred by customers, owing to direct readings being obtained without the need of any calculations and also owing to their simplicity. On page 245, under the table giving the limits of observable temperature adopted by the Commission, it will be seen that commutators and slip-rings are bracketed together with a final permissible temperature of 90° C. The mechanical construction of slip-rings usually takes the form of a bronze ring shrunk on to a mica-insulated cast-iron hub. With such construction a very high temperature is possible without any fear of the rings becoming affected, whereas with commutators of the usual construction it is extremely difficult to obtain anything like equal expansion of all parts, with the result that a high temperature rise on the commutators is to be deprecated, as trouble may then be expected with high bars, loosening, etc. It will therefore be interesting to hear Mr. Everest's remarks as to the reasons which made the Commission bracket together such dissimilar parts as commutators and slip-rings under a common heading. The I.E.C. Rules described by Mr. Everest, although taking care of possible damage to electrical machinery due to high temperatures, have not made any attempt to define Rules for the sparking limits of continuous-current machines. With continuous-current machines this is quite as important as the standardization of safe temperature limits, and will now be more necessary than ever if the overloads at present universally given with such machines are excluded. In fact there are many cases where continuous-current machines are called upon to give a very heavy

output for such short periods that the temperature rise Mr. Stein does not enter into the calculations, the limits being sparkless commutation and mechanical strength. I should like to associate myself with Mr. Larke's remarks as to the inadvisability of rating motors on a kilowatt instead of a brake-horse-power basis. Such a rule would undoubtedly only help to confuse consumers, who very often have a fair idea of the brake-horse-power required but would regard a kilowatt rating as meaningless.

Dr. T. F. WALL: I take it that the most important point under discussion is the temperature which the cooling air is to be assumed to attain in any temperate zone in order that the temperature rise allowed by the Commission may be consistent with the limiting values given in the table. On looking at this table I noticed what appeared to me to be the very high values allowed for the limiting temperatures. So far as I know, one of the most extensive pieces of experimental work carried out in connection with the effect of heat on insulating materials is that described in Mr. Rayner's paper.* In view of the data there given and briefly summarized by Dr. Glazebrook who opened the discussion, I think we may conclude that there is not much margin of safety when the values given in the table are adopted; and it would seem desirable that these values should on no account be exceeded. The severe conditions to which coils are exposed in practice, the alternate heating and cooling, the absorption and drying out of the moisture, which as Mr. Everest showed takes place even in well-shellaced coils, the leakage currents due to the presence of moisture, and the impurities in the atmosphere, all have a deteriorating influence on the insulation, and it would seem to be imperative that the mechanical strength should not be endangered by the temperature rise. Such considerations would seem to suggest that something of the nature of a factor of safety would be desirable. Certainly the highest temperature likely to be experienced in any temperate climate should be taken in conjunction with the table to fix the temperature rise. That is to say if a temperature of 40° C. is not uncommon, then if the value of 35° C. is taken as fixing the permissible value, the temperatures given in the table will in some cases be exceeded, and the danger zone will then be reached. With regard to the rating of motors in kilowatts instead of horse-power, I might suggest as a compromise that the kilowatt rating be adopted, and in those cases in which a customer is better satisfied to know what the horse-power is, this rating might also be given on the name-plate.

Dr. A. H. RAILING: It is a great pleasure to me, and it must be a source of great satisfaction to Dr. Kapp and Mr. Everest, who have represented us at the International Conference, to see that the practically unanimous opinion of all those who have taken part in this discussion is for the greater margin of safety, thereby fully supporting the attitude which our delegates have taken. Personally, I entirely agree that it would be wrong from a scientific point of view to reduce the margin of safety, and I agree to the higher temperature rise. As far as I am aware the tests that form the basis of our figures for various insulating materials have been carried out under normal conditions. In practice, however, there must be many factors adversely

* *Journal I.E.E.*, vol. 34, p. 613, 1905.

Dr. Railing. influencing the life of insulating material and thus reducing the present factor of safety. To mention one or two points: it seems to me that the life of any insulating material does not depend on the temperature reached at any given time, but also on the maximum temperature differences to which the material is subjected. For instance, a motor standing still at night with the temperature at, say, 20 degrees below zero, and running during the daytime with a temperature rise of, say, 50 degrees C. in an atmosphere at 40° C. will have to undergo a maximum temperature variation of 110 degrees. I suggest that the life of the insulating material undergoing such variations of temperature will very probably be less than if the total temperature variation were smaller, although the maximum temperature reached might be identical in the two cases. I assume further that the tests were carried out in an atmosphere which was either dry or contained a normal degree of humidity. I should be glad to hear whether results are available which show how the rise in temperature is affected by the varying degree of humidity, since my experience seems to show that temperature rises vary by a certain amount with a varying degree of water vapour in the atmosphere. I remember that when I was in charge of a test-room the tests carried out in a damp atmosphere seemed to show a slightly smaller temperature rise than those carried out in dry weather. Now it seems clear to me that just as Dr. Kapp showed us that the cooling effect on a body depends upon the speed with which the cooling medium passes that body, or, in other words, on the number of particles that pass in a given time, it must equally depend on the specific heat conductivity of the cooling material, which of necessity must be different for water vapour and air, never mind to what extent. Apart from this consideration of humidity as affecting the actual cooling process, and therefore the temperature rise which can be prescribed, there is no doubt that the life of the insulating material in climates where frequent evaporation and condensation take place must be affected, and therefore that we should use a certain factor of safety in the case of figures obtained without taking such conditions into consideration. A third point is that in all moving machinery the insulating material is to a certain extent subject to varying stresses, which I suppose have not been taken into consideration in the curves. Dr. Kapp has just shown us that, with the higher temperature rise suggested, we should go dangerously near the knee of the curve. If in addition to this we take into consideration facts like those mentioned above, which must be allowed for in practice, it shows how necessary it is to have the factor of safety for which our delegates have stood out, in the form of a smaller temperature rise.

The above is from the theoretical point of view; but I should like to add that the greater margin is equally desirable from the point of view of the purchaser and the manufacturer. We are expending hundreds of thousands of pounds in power stations all over the world. In any of these systems the cost of the generators is an almost negligible quantity. The difference in cost between a safe machine and one which runs dangerously near the permissible limit may be £100 or £200, that is to say, a fraction of 1 per cent of the capital outlay. For such a small sum it is either common sense or commercially good practice to run the risk of breakdowns, which of

course bring discredit to the undertaking? If we take into consideration the driven machinery, the cost of the same, and the loss in output if any breakdown occurs, we see that the cost of the motors represents a similar small percentage of the total capital outlay of any manufacturing establishment, and that it also pays there to have reliable motive power. We should not hesitate in the case of any big plant to spend in insurance sums representing more than the difference due to a 10 degrees less rise in temperature. I therefore consider that it is utterly unsound from a technical and a commercial point of view to work, for the sake of a negligible increase in the capital outlay, with factors of safety which undoubtedly are on the low side, and which if adopted would only in the end tend to discredit electricity as a motive power. In conclusion, I may say that we can congratulate our delegates on the way in which they have tackled this problem; that they have our full support in the attitude which they have taken up; and that we are of the firm opinion that after carefully considering these proposals the Commission will finally decide in favour of these points, on which of course the whole working of the rules depends. I am of the opinion that the adoption of these proposals and of the whole of the rules would be to the universal benefit of the electrical industry and to the application of electrical machinery in all countries.

Dr. C. C. GARRARD: I cannot quite understand the lengthy arguments which have been put forward with regard to the reference, or standard, air temperature. It seems to me that this is only a roundabout and somewhat confusing method of fixing the standard temperature rise. It is clear, since it has been granted that the temperature of the cooling air during test has no effect on the temperature rise, that machines can only be compared with each other on the ground of temperature rise. Three possible I.E.C. ratings have been mentioned to-day, viz. the temperate zone rating (based upon the nominal air temperature of 35° or 40° C.), the torrid zone rating, and the northern or arctic zone rating. This is a very bad beginning for the establishment of a standard or international rating. Some people seem to have gone to great trouble to make meteorological investigations over the greater part of the world. This seems to me to be somewhat absurd since much greater variation of temperature may be found in one building or ship—say between the stoke-hole and deck, in both of which positions electric machinery may be placed. The idea appears to be prevalent that having fixed the limits of observable temperature it is possible to devise a rating which would ensure that this permissible temperature will never be exceeded. This is clearly impossible. It would be possible, of course, so to arrange the rating that in the majority of cases the highest allowable temperature would not be exceeded. My point is, however, that the method of referring to a standard temperature for cooling air is confusing. The real question is whether the standard temperature rise shall be, say, 60 degrees C. or 55 degrees C. Having fixed this, there would only be one rating, as of course there must be if it is to be an international rating. The table of limits of observable temperature given on page 245 would then be very useful to the user in determining what machine to use in any given circumstances. He

er. would know the surrounding air temperature, and this added to the standard temperature rise would give the final temperature which would be attained. He would then know from the table on page 245 whether the material of which his machine is constructed would withstand this temperature or not. In fact, this method of investigation must always be used. It is not possible to fix any standard rating so that the purchaser would be safe in installing in any position a machine purchased as being in conformity with such standard rating. Such action would have the result that instead of the factor of safety being higher the hotter the location, it would, in fact, be lower than in a colder situation. In conclusion, I think it would be much better to make it quite clear that we are simply aiming at fixing an international standard of temperature rise and that there will not be several I.E.C. ratings but only one.

er. Mr. N. B. ROSHER: I consider that the work already done by the Commission in fixing the limits of observable temperature for the various parts of electrical machinery is of very great importance, but I agree with Dr. Kahn when he pleaded that the rating of machines should be no higher in the future than at present. If the Commission ultimately adopt 40° C. as the ambient temperature, the rating of machines will be considerably higher than at present. My objection to the higher rating is chiefly that a very large percentage of the motors used for industrial purposes drive line shafting to which additional machines are frequently added. If the motors used for these purposes are highly rated there will not be the same margin of power as at present. Of course it may be argued that this can and should be guarded against by installing a motor of liberal capacity for the work it has to do, but speaking from considerable experience I maintain that this course is not generally adopted unless the purchaser has expert advice. In any case the chief requirement of a motor is that it should prove reliable in service, and this is the more likely to happen if the machine is rated liberally rather than up to its maximum safe limit. It is gratifying to note that the present unsatisfactory condition of affairs as to overload, and the illogical permissible difference in temperature rise between protected and totally enclosed motors, will disappear under the proposed new rating. With regard to the table of limits of temperature for various parts of machines adopted by the Commission, it seems to me very undesirable that the figure for bearings should be as high as 80° C. It may not matter for large machines which are under constant supervision, although even there I think it too high. It is in the case of motors which are installed in out-of-the-way positions, or where an inspection is made at only infrequent intervals, that such a high limit as 80° C. is so undesirable. Should there be any little hitch in connection with the bearings of such motors, as is quite possible, the temperature would rise and the motor might easily break down if the ambient temperature approaches 40° C.

son. Mr. H. R. HUDSON: I should like to draw attention to one point which, although only indirectly connected with this discussion, has very considerable importance in connection with the fixing of maximum permissible temperature rises. I refer to the employment of fans on the rotating parts of ordinary "protected type" and "enclosed ventilated type" industrial motors. Mr. Everest has stated that

the I.E.C. standard of quality has now been established Mr. Hudson. as regards the temperature and, therefore, the life of a machine, and also that provided the I.E.C. rating be specified, a buyer of standard machines could compare, without misunderstanding or possibility of mistake, tenders received from various makers, even from different countries. Now, every designer is familiar with the reduction in cost for a given temperature rise which is obtained by the use of well-designed fans on the revolving parts of motors of normal speeds, and this without an appreciable reduction of efficiency. We are, unfortunately, equally familiar with the fact that, in five cases out of six, motors are installed in such positions and under such conditions that after a few months' running the ventilating passages and the interstices between the armature coils of a fan-ventilated motor are so clogged with dirt that if a full-load test be taken the maximum temperature rise will be found to be 10 to 15 per cent higher than when the motor was first installed. This is not the case with machines relying on natural ventilation. Hence specifying I.E.C. rating would not in all cases establish a standard of quality either as regards temperature or life, unless accompanied by some proviso that the temperature limits shall not be exceeded when the machine is tested after a certain period of running under actual service conditions. Such an arrangement would of course be commercially out of the question, and it would therefore be very desirable if the Commission could see its way to define clearly the various types of machines. The Standardization Rules of the British Electrical and Allied Manufacturers' Association do not differentiate between enclosed ventilated machines with natural ventilation and enclosed ventilated machines with ventilation induced by means of a fan on the revolving shaft, but I certainly think that in the interests of the buyer and also from the point of view of placing all manufacturers of whatever nationality upon an equal footing when quoting for enclosed ventilated machines, it is most desirable that machines with natural ventilation should not be placed in the same category as machines with fan ventilation. The matter seems to me to be quite as important as discussing whether the maximum air temperature in the temperate zone should be taken as 35° C. or 40° C. I sincerely hope that the Commission will give the subject of the definition of types of electrical machines its earnest consideration.

Mr. H. M. HOBART (*communicated*): In the preliminary Mr. Hobart. draft of a pending revision of the Standardization Rules of the American Institute of Electrical Engineers the plan has been followed of adhering to the I.E.C. Rules to the extent to which the latter have now been completed, and to incorporate their spirit in dealing with the classes of machines and the various features for which they do not yet provide. The preliminary American Institute draft divides rotating machinery into two groups, relating respectively (a) to machines for pressures up to and including 4,000 volts, and (b) to those for pressures above 4,000 and not exceeding 14,000 volts. For these two classes it is assumed that the internal drop in temperature will be respectively 10 degrees and 20 degrees. That is to say, it is assumed that there will be places in these machines where the insulation will be subjected to temperatures exceeding by 10 degrees and 20 degrees respectively the highest temperatures

Mr. Hobart. which can be "observed" with the methods of measurement recognized in the rules. For stationary transformers the internal drop in temperature is assumed to be 10 degrees, irrespective of the pressure for which the transformer is wound. The construction of modern transformers is on such lines that the internal drop in temperature is no greater in a 100,000-volt transformer than in a 1,000-volt transformer. In fact, if anything, the small low-pressure transformers are of such compact construction as to lead to the liability of greater internal temperature drops than would occur in large extra-high-pressure transformers. However, the value of 10 degrees for the internal drop in temperature may be deemed entirely appropriate for all transformers. Were we to confine to mercury-thermometer measurements the methods by which the "observable" temperature should be obtained, these assumed internal drops would often be inadequate. But it is proposed to encourage the use of much more searching methods of arriving at the "observable" temperature, such as by the measurement of the resistance of the windings, or even by the use of embedded search coils, or thermocouples. In the preliminary draft for the American Rules the I.E.C. values for the highest permissible limits of "observable" temperature have been adopted. It has, however, been considered desirable to draw attention to the values of the "hot-spot" temperature, and it is proposed that the American Rules shall contain columns giving the values of these "hot-spot" temperatures in addition to the corresponding values of the highest permissible "observable" temperature. The values which have been internationally adopted for the highest "observable" temperatures represent approved practice for continuous running, if associated with such provisions as shall insure that they are never exceeded. A very small exception to this sweeping generalization is made. This exception relates to the rule that the duration of a test of a machine for continuous service shall be prolonged until the temperature of the machine and that of the cooling air does not increase by more than 1 degree per hour. The temperature rise at this stage of the test shall be taken as the "observable" temperature rise corresponding to continuous operation. As a consequence of this rule, the so-called highest "observable" temperature will, in reality, be exceeded by from 1 to 2 degrees according to the size and type of the machine. This excess may be reasonably considered as covered by the values allocated to the internal temperature drop. While these are taken as nominally 10 degrees and 20 degrees respectively, one or two degrees of this 10 or 20 degrees may be considered as reserved for meeting the above rule, the remaining 8 or 9 degrees on the one hand, or 18 or 19 degrees on the other hand, corresponding to the actual difference between the "hot-spot" temperature and the "observable" temperature.

This expression of approved practice as regards the limits of "observable" temperature requires to be accompanied by international agreement in the matter of an "ambient temperature of reference" in order to secure the commercial advantages of an international rating. For the American Rules the prospective international ambient temperature of reference" of 40°C. is adopted. Data of *shade* temperatures from all over the temperate

zone afford ample evidence that no lower value could be adopted consistently with the international recommendation that the standardized limits of "observable" temperature shall never be exceeded. This recommendation is not only international but it has already been incorporated in paragraph 18 of the new standardizing rules of the Verband Deutscher Elektrotechniker, which include the following statement:—

"Die höchsten zulässigen Temperaturen sind in Spalte 2 angeführt.

"Es wird angenommen, dass die Temperatur der Umgebung 35°C. nicht überschreitet.

"Dementsprechend dürfen die Temperaturzunahmen in der Spalte 1 aufgeführten Werte nicht überschreiten."*

Although in these V.D.E. Rules the ambient temperature is taken as 35°, this is accompanied with the statement that 35° shall never be exceeded. Since the approved "observable" temperature rises set forth in the V.D.E. Rules are values which, when added to 35°, give the highest permissible "observable" temperatures, it is clear that when the ambient temperature is greater than 35° the highest "observable" temperature will be exceeded by an equal amount. *Shade* temperatures approaching and exceeding 35° are so common in all parts of the temperate zones that there is no escape from the conclusion that in the neighbourhood of electrical machinery the ambient temperature is frequently between 35° and 40°. To declare it to be 35° is futile if (as is the case) it actually attains values several degrees greater, since this will occasion the temperatures corresponding to approved practice at times to be exceeded by several degrees, which conflicts with the international agreement that the approved observable temperatures are to be considered as values which shall never be exceeded.

The work so far accomplished on the revision of the American Rules is chiefly due to Messrs. Lamme, Steinmetz, Merrill, Robbins, and Powell, the members of the 1912 sub-committee dealing with the revision. The 1913 sub-committee is at present engaged in drawing up sections dealing with "Efficiency and Losses," with "Performance Tests with Load," and with "Regulation." These are subjects which have not yet been included in the I.E.C. Rules, and it is the desire of the Committee having the matter in hand to endeavour so to frame these Rules as not only to conform with the most approved practice, but also to be on such lines as shall be in agreement with the best work already done in other countries. A great deal of standardization work has been done in Great Britain and in Germany, and it is desired to take this into careful consideration in all sections of the American Rules.

Mr. A. R. EVEREST (*in reply*): The discussion has brought out a few points on which some explanation seems necessary. With regard to the suggestion that a definition of commutation limits is needed, it may be said that the International Electrotechnical Commission has proposed to take up this question immediately following that of temperatures.

In connection with the point raised by Mr. Siebs as to

* "The highest permissible temperatures are given in column 2.

"It is assumed that the ambient temperature does not exceed 35°C.

"Accordingly the rise of temperature must not exceed the values given in column 1."

est. the desirability of allowing the same temperature limits on such dissimilar structures as commutators and slip-rings, at first it was proposed to allow higher limits for slip-rings, but they were finally reduced to those specified for commutators, the reason being that brushes of similar character are employed in both cases, brush deterioration largely determining the permissible temperature.

Dr. Garrard referred to three ratings, namely, for temperate, torrid, and arctic conditions. It is only proposed at present to establish an international rating suitable for temperate countries. Machines intended for tropical conditions would have to be rated specially, so that the limits of ultimate temperature given in the table on page 245 should not be exceeded.

Mr. Hudson mentioned machines arranged with fan ventilation, which become clogged and overheated after a short period of service. In connection with his reference to the Standardization Rules of the British Electrical

and Allied Manufacturers' Association, it may be pointed out that those rules differentiate between machines according to the mesh of the screen placed over the ventilating openings, the intention being that those constructions which are liable to become clogged shall be rated not as ventilated but as totally enclosed machines.

Dr. Railing referred to variation in the cooling properties of the air according to its humidity. The difference between the heat-absorbing capacity per degree rise of temperature when saturated and when perfectly dry is about 17 per cent with air at 40° C. and much less at lower temperatures. Remembering that even on a "dry" day the humidity is usually from 60 to 80 per cent of saturation, it would appear that the actual variation between dry and wet days becomes negligibly small. But if the machine itself has become damp by storage in a humid atmosphere, it may show a lower temperature rise in operation until it has become thoroughly dried out.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 8TH JANUARY, 1914.

Proceedings of the 560th Ordinary Meeting of The Institution of Electrical Engineers, held on Thursday, 8th January, 1914—Mr. W. DUDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 18th December, 1913, were taken as read, and confirmed.

The list of candidates for election and transfer approved by the Council for ballot was taken as read, and was ordered to be suspended in the Hall.

Messrs. E. W. Moss and C. F. B. Marshall were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows:—

ELECTIONS.

Member.

Hersfeld, Rudolf.

Associate Members.

Denham, John.

Eason, Alec Birks.

Evans, Stuart.

Field, Arthur Mottram Cox.

Oswald, William James.

Pressland, Clifford Thomas.

Tivey, John Proctor.

Wade, Charles Frederick.

Associate.

McKenzie, Ernest.

Graduates.

Carr, Francis.

Fasnacht, Harold.

Joseph, Fred Bernard.

Mavor, Albert John.

Morgan, Joseph.

Platt, Frank Cuthbert.

Simpson, Francis Augustus.

Smith, Allen Egbert.

Students.

Baker, Hubert George.

Bottone, Reginald Amadeus R.

TRANSFERS.

Associate to Graduate.

Waygood, Oscar Candish.

Student to Associate Member.

Archer, John Oliver.

Broadhurst, Francis Arkle.

Hollings, Gordon Alfred.

Le Feuvre, Charles George.

Manners-Smith, John Alexander.

Martin, Cyril Arthur.

Nadejde, Horia Toan, M.Sc. (Eng.).

Papazian, Hapet.

Brunton, Theodore Stuart.

Dawes, Ronald Richard.

Field, Lance Henry.

Jones, Walter John.

Langridge, Archie William.

Mann, Frank Harris.

Odgear, James Edward.

Paul, Bangsidiari.

Singh, Prem.

Skevington, Francis Kerr.

Sleigh, Charles Crofton.

Vercker, Henry Connell.

Ward, Percy.

Associate Member to Member.

Cartwright, Cecil Leonard.

Marsh, Francis Richard.

Maxwell, John Maxwell Scott.

Moore, Edward Ernest.

Associate to Member.

Ashman, William Henry.

Richards, Arthur Francis Ward.

Graduate to Associate Member.

Mann, Thomas Sidney Lanyon.

Potts, Thomas Frederick.

Roxburgh, Andrew Kean.

Taylor, James Ardern.

Thompson, John Lindley, M.Sc.

Student to Graduate.

Brennan, Leslie J.

Gray, Ronald.

Mitra, Kshitish Chandra.

Tisch, Walter Clements.

Wilkinson, Sam.

Wyatt, Esdaile.

A paper by Mr. B. Welbourn, Member, entitled "British Practice in the Construction of High-tension Overhead Transmission Lines" (see page 177), was read and discussed, and the meeting adjourned at 10.5 p.m.

REACTANCE AND REACTANCE COILS IN POWER CIRCUITS.

By E. P. HOLLIS, Associate Member.

(Paper first received 29th August, and in final form 3rd December, 1913; read before the NEWCASTLE LOCAL SECTION, 26th January, 1914.)

SUMMARY.

In this paper the author proposes to review the part played by inherent and added inductance in the phenomena that occur in electric power circuits.

INTRODUCTION.

One of the most remarkable events in the recent history of electrical engineering has been the complete change of opinion of electrical engineers on the question of the use of reactance in alternating-current circuits. Until recently engineers endeavoured to avoid reactance in all its forms; but it is now realized that reactance has virtues hitherto unsuspected, which if turned to account confer important benefits on electrical power supply systems. In 1907 the author had evidence of the general opposition to reactance on the usual grounds of the likelihood of resonance, when in a paper read before the Newcastle Local Section he advocated for certain purposes the insertion of reactance coils in alternating-current circuits. Reactance coils are to-day being used not only for the purpose then suggested, but also where their introduction has far more vital consequences.

In 1900 when the rotary converter first came into prominence, reactance proved a valuable auxiliary, and this was probably the first occasion on which large reactance coils were used in power circuits. The rotary converter at that time gave a fixed voltage ratio, and offered no inherent method of regulating the pressure on the continuous-current side. This disadvantage was soon remedied by inserting reactance coils in the low-tension alternating-current circuit. External reactance coils were often installed, but as patent rights restricted the use of actual coils it was found possible in the majority of cases to design the transformers with sufficient internal reactance to meet the situation without lowering the power factor too much.

THE NEED FOR REACTANCE COILS IN POWER SUPPLY.

Recent progress in electric power supply has marked out for reactance coils a promising future, and it is probable that they will prove of assistance in solving some of the problems that beset engineers concerned with the operation of extensive power supply systems.

One of the most pressing of these problems is that of limiting the excessive current that may momentarily flow in the case of a short-circuit. There is also a problem to which the author attaches equal importance, but to which far less attention is paid, namely, increasing the stability of power systems so that they can better withstand internal disorders.

As is well known, the short-circuit current of a generator reaches far larger dimensions than might be supposed at first sight, for the true short-circuit current is very different from that shown by the ammeter in a short-circuit test at the works. The latter reading is of the order of from three to five times the full-load current.

It has, however, for some years been known that in the case of a generator in which no special care had been taken to ensure a high self-induction, the current rises at the first instant of short-circuit to something like 30 times the full-load current. What exactly happens on short-circuiting a large turbo-alternator has been discussed at some length in recent electrotechnical literature, so that the author will content himself with a few brief remarks on this question.

There are five main effects which play a part in determining the value of the momentary short-circuit current of a generator. These are the self-induction of the armature, the armature reaction, the generation of eddy currents in the rotor, the transformer action between the armature and field coil, and lastly the resistance and surge impedance of the short-circuit path. It is the self-induction of the armature that plays the leading part in limiting the short-circuit current. The first rush of current is controlled by little more than the self-induction of the armature and the resistance of the circuit, which act practically instantaneously in stemming the rush of current. The eddy currents and the armature reaction, however, are unfortunately very slow in taking effect at such a critical moment. On the other hand, the transformer action is also slow. The armature reaction gradually asserts itself, sometimes attaining its full effect only after 15 seconds or more, when the initial rush of current has passed and the damage is done.

The eddy currents too are dilatory in their counter-effect; they reach enormous values, however, both as regards current and voltage, and they have been observed to flash over in search of a new path. Eddy-current effects have been recorded equivalent to 2·4 times the armature reaction.

Little is known of the effects of transient resistance upon the short-circuit current, but since the pressure drop due to resistance would be 90 degrees out of phase with the inductive voltage, any increase in the resistance of the circuit would have to be extremely large in order to make itself felt in limiting the short-circuit current.

The phenomena in connection with the field flux are very complicated. The transformer effect at the moment of short-circuit is such as to send surging through the field coils a current which has been observed to have a peak equivalent to 10 times the normal field current. This change in the field current, and consequently in the field flux, appears to assist the armature current. One theory which has been advanced balances the effects of the eddy currents and the field flux changes against each other; but there appears to be no justification for such a theory. Apart from armature resistance, practically everything depends on the ability of the self-induction of the armature to limit the current. Recent developments in design have tended to reduce the self-induction of the armature,

with the result that in a modern turbo-generator, unless very special endeavours are made, the leakage reactance (*i.e.* that due to self-induction only) represents only from 10 to 15 per cent of the synchronous reactance measured on the short-circuit test. It is not surprising then that the r.m.s. value of the momentary current may attain 20 to 30 times the normal full-load value (*i.e.* have a short-circuit ratio of 20 to 30) as has been demonstrated by experiment. Nowadays, however, designers have paid special attention to increasing the self-induction of the armature, and by various devices have increased the ratio between the armature inductance and the whole inductance.

The part played by eddy currents and fluctuations in the field flux in damping the first few waves is, like that of the armature reaction, not very great. Nevertheless, they have a not inconsiderable effect on the short-circuit current. Taking the tests which have been made upon short-circuited generators, the values of the currents actually attained are less than would be observed were leakage reactance the only limiting factor. Indeed, there seems to be a transient reactance operating at the moment of short-circuit, which adds something like 60 per cent to the leakage reactance of the armature and reduces the current to a smaller value than it would otherwise have attained. This value is nevertheless high, and is shown by experiment to be of the order of 20 to 30 times the full-load current. The rush of current in the field coils which occurs in the case of a short-circuit may conceivably give rise to a breakdown in them.

If one considers the destructive power produced in the case of such a short-circuit, it becomes obvious that something should be done to limit the flow of current. Taking a power-supply system in which generating plant to the amount of about 50,000 kw. is in use daily, a short-circuit between phases near the power station might mean a current of 120,000 amperes, which of itself would exert sufficient mechanical force to cause serious damage to cables, busbars, and connections. On the switches, also, its action would not be negligible. Of course, while the closed circuit existed the power would be of small amount, but as the switch in attempting to cut off the short-circuit begins to open, the power rises to a high value. With the switch closed the current is 120,000 amperes, and the voltage negligible; and with the switch open the current is zero and the voltage is the full phase value; but between these positions there is a moment when the amount of power is exceedingly large. It can be expressed in kilovolt-amperes for one phase by half the product of the maximum current and the maximum kilovolts; which comes to over half a million kilovolt-amperes. No doubt a specially designed circuit-breaker would deal with that amount of power, but the chances of trouble in a switch of standard design are very great.

It appears, then, that a good case can be made out for imposing some limits to the amount of short-circuit current. In many instances reactance coils are being successfully employed for this purpose.

REACTANCE COILS AND THE STABILITY OF POWER SUPPLY SYSTEMS.

Apart from their ability to relieve the power station of the shocks and stresses due to short-circuits, reactance coils largely promote the stability of a system, and it will

probably happen that when the time comes for the operation in parallel of distant large power stations reactance coils will become essential.

Between alternators working in parallel there is a continual interchange of current, which tends to keep the two machines in step. The current which flows, however, is not all available for promoting parallel running. As is well known, only its synchronizing component is so available, and anything that increases that component also improves the parallel running of the machines. The reactance coil does this, for the current flowing between the machines being more or less in quadrature with the main voltage, has to be brought more nearly into phase with the voltage before it can be useful in promoting synchronism. In the absence of adequate reactance the synchronizing component of this current is only small. The presence of reactance, however, greatly increases the value of this component. Usually the inherent leakage reactance of the machine sufficiently exceeds the resistance to ensure that machines in the same station run fairly well in parallel. The ratio of reactance to resistance deemed necessary for this purpose is about three or four to one. Where the machines have considerable resistance between them the leakage reactance is less than the resistance, and bad parallel-running results. Not only, then, will reactance improve the running of the machines in the power station, but it adds materially to the stability of the system as a whole by assisting the synchronous machinery at a distance—whether generating or motoring plant—at critical moments. Hitherto the reactance of the transformers and transmission lines has only been available for this purpose.

In other directions also reactance promotes stability. Schuchardt and Schweitzer's² experiments demonstrated that with adequate protection the generator speed did not drop more than 2 per cent on short-circuit. Moreover, the voltage of the generators does not decrease so much; the liability of electrical machinery connected to the system to fall out of step is therefore lessened—a point of considerable importance.

REACTANCE AND ITS EFFECT ON THE CONTINUITY OF SUPPLY IN POWER STATIONS.

For some years attempts have been made to promote continuity of supply in power stations by adopting the so-called "unit" system of running. In a previous paper read before the Newcastle Local Section of the Institution, the present author, writing at a date when the system had never been put into operation in this country, discussed its merits and defects. Actual experience confirms the views which he then expressed. But the unit system goes a very small way towards promoting the reliability of the system; for unless the expenditure be very great the generators must run in parallel, either through the busbars or the network, and all the troubles incident to a breakdown on the busbar side of a grouped station are repeated in the case of a system operated on the unit principle. The boilers, too, must be operated in parallel.

Power-limiting reactance coils are valuable not only when inserted in the phase leads of the generator, but also between the busbar sections. If the coils are merely

² *Transactions of the American Institute of Electrical Engineers*, vol. 30, part 2, p. 1143, 1911.

inserted in the phase leads, when a number of machines are running in parallel with the "star-point" of only one machine earthed, that machine takes the whole of the current of a short-circuit between one phase and earth, and in consequence it has to withstand all the stresses. Should, however, all the generators be connected to a neutral busbar which is connected to earth through a resistance or reactance coil, the short-circuit current divides between all the machines, and while the portion taken by each machine may be comparatively small, the aggregate may attain undesirable dimensions.

Reactance coils inserted in the busbars, however, limit the amount of power which a group of machines can supply on short-circuit to a feeder the normal load of which is being supplied in part by another group of generators. The station busbars would be "ring" connected and a set of reactance coils would be placed between each group of machines. Thus the perfect unit system can be more nearly attained by using reactance coils.

The amount of reactance to be used between the busbars is determined by several considerations. First, it must be high enough to prevent a serious fall of pressure in its section in the case of a short-circuit on another section; and, second, it must not interfere to any appreciable extent with the current that must necessarily pass between the various busbar sections to accommodate changes of load or to promote synchronous running. Circumstances peculiar to every case fix the exact value of the reactance, for which 20 per cent* of the generator capacity of each section would be an approximate figure.

Reactance coils in feeder circuits naturally follow for limiting the power on short-circuit in underground and short overhead lines. In the case of interconnecting mains between power stations, reactance is also desirable to promote parallel running, especially where the resistance of the feeders is large.

INTERNAL AND EXTERNAL REACTANCE IN GENERATORS.

Whether internal or external reactance is to be employed in the case of a generator is a further ramification of the main problem. Dynamo designers have occasionally taken exception to the idea of external reactance, and have declared their ability to embody all the necessary reactance in the machine itself. That may often be a difficult matter for very obvious reasons, since the whole of the reactance, say 15 per cent, in order to be effective in preventing rushes of current in the case of short-circuits, must be of the leakage or self-inductive variety.

Apart from questions of design, it is evident that a considerable proportion of the inductance must be external to the machine. One of the duties imposed upon a reactance coil is that of protecting the generator itself from a heavy influx of power from the system in the event of a burn-out. Such a burn-out occurring near the terminals might rob the generator of all or a large part of the reactance on which it depended for its protection. So that in the event of the reactance being wholly internal little protection will be afforded to a broken-down generator, and at least some of the reactance must be external. Perhaps an equal division, internal and external to the generator, would meet most cases.

* The value of the reactance coil is most conveniently referred to in terms of the percentage drop of voltage across its terminals with full-load current flowing.

REACTANCE CIRCUIT-BREAKERS.

The heavy duties which the modern oil circuit-breaker is called upon to perform present severer difficulties as the size of the generating unit increases. So much so that cases are on record where two circuit-breakers have been installed in parallel. For rupturing heavy currents a "resistance" circuit-breaker was developed in which instead of the current being broken immediately, a number of auxiliary steps opened first and inserted a gradually increasing resistance until finally the main contacts opened and completely broke the circuit. In this manner the current was gradually reduced and the duty imposed upon the main contacts was lessened. Although theoretically sound, the principle introduced difficulties in practice. The power absorbed in the resistance caused a large amount of heat to be generated, and the problems of insulating such a resistance were not easy of solution. Reactance, however, is a preferable alternative to resistance, and it has been successfully employed in this direction. Instead of a number of steps, as in the case of a resistance, only a single step is employed. The reactance coils are so connected that they may be placed in series with the line, the load, and the main contacts; but with the circuit-breaker closed they are short-circuited by auxiliary contacts. These contacts are the first to open and thus connect the coils in series with the line and reduce the current before the main contacts separate. These main contacts then break the load-current at its reduced value.

REACTANCE COILS AND THE SWITCHING-IN OF GENERATORS AND MOTORS.

The dangers attending the synchronizing of large turbo-alternators have long been recognized and the sticking or slow operation of an oil switch may imperil the safety of a large generator. In several instances abroad, operating engineers have gone to the other extreme, and by inserting reactance coils between the incoming generator and the busbars have freed themselves from the anxieties of synchronizing. These coils have been designed to allow the generator to be switched in when 180 degrees out of phase with the busbar voltage without undue stresses being caused. Under these circumstances it is unlikely that a machine unprotected by reactance coils would remain undamaged, since both the current and voltage conditions severely test the generator. The resulting pressure between the busbars and the generator would be twice the generator voltage, but the pressure wave would certainly not oscillate about the neutral axis. On the contrary, it might oscillate so far above it that the maximum pressure to earth would be four times the normal.

With the development of the so-called "self-synchronizing" synchronous motor, it is not improbable that reactance coils will be employed to limit the rush of current on switching in, taking the place of more complicated starting devices.

THE EFFICACY OF REACTANCE COILS.

Assuming that some limit should be set to the amount of short-circuit current, it still remains to be shown that the insertion of external reactance can effect the desired reduction in current. Experimental results at the Fisk-street station, Chicago, clearly indicate that reactance coils do

materially reduce the short-circuit current. An observed short-circuit current of 30,000 amperes with no external reactance but 2 per cent of internal leakage reactance was reduced to 19,400 amperes by 3.93 per cent of external reactance, and to 15,800 amperes by 6.26 per cent. Durgin and Whitehead² have derived a formula from which the maximum short-circuit current can be calculated by simple low-voltage short-circuit tests. Applying this formula, curves have been obtained from which it is an easy matter to deduce the effect of a short-circuit with varying values of the reactance. Starting in a particular instance with a short-circuit current of 27 times the full-load value, 6 per cent of reactance would reduce it to 15 times, and 15 per cent to about 9 times, the mechanical stresses on the end-turns being respectively 729, 225, and 81 times the full-load value. The conclusion reached as the result of this investigation, namely that the total leakage reactance should not be less than 15 per cent, seems to have every justification.

As might be expected, it appears from Durgin and Whitehead's formulae that the effect of resistance in circuit with a fault diminishes the part played by the reactance coils in limiting the short-circuit current. That, of course, is all to the good; it is in the worst conditions, when there is a very low fault resistance, or a low impedance of the system short-circuited, that the reactance coil is most needed. One fact in connection with the tests taken at the Fisk-street station is of considerable importance. The tests demonstrated that the presence of steam on the turbine in no way affected the results, i.e., the short-circuit energy came from the rotating mass of the machines. The author inclines to the opinion, then, that on a large power supply system, where there is not only the rotational energy of the turbines, but also that of all the other synchronous and asynchronous machinery, the short-circuit current must be far larger than the calculations and experiments on a single machine would lead us to expect.

REACTANCE AND THIRD-HARMONIC CURRENTS.

One of the earlier uses to which it was suggested to put reactance coils in alternating-current power circuits was that of limiting the flow of the third-harmonic currents between three-phase star-connected generators. To limit such currents many engineers have resorted to the earthing of only one generator "star-point." In order to limit the short-circuit current a resistance and now a reactance are included in the earth circuit. But this suggestion of using reactance was made in the early days when the possibility of troubles due to resonance were ever present in the engineer's mind. However, the reactance which is now embodied in the generator or inserted in the phase leads for quite another purpose, also serves to limit any third-harmonic currents that would tend to flow when all the "star-points" of the generators were connected together. The triple impedance offered to the third harmonics by virtue of their frequency is doubled, since the reactance of the phase windings and that in the phase leads have both to be traversed. Calculations based on the low figure of a 10 per cent total leakage reactance (not including armature reaction, which does not affect the third harmonics) show that the danger of the third-harmonic current reach-

ing 20 per cent of the full-load current is remote, even when operating with widely differing values of the excitation. Such a current may at first sight appear dangerous, but in reality its effects are negligible. Taking as an example a 10,000-k.v.a. 11,000-volt generator, having a total leakage reactance per phase of 10 per cent external and internal, with a third-harmonic voltage equal to 10 per cent of the fundamental voltage between the star-points of the generator, the heating loss would be increased by 1 per cent. Thus a 10 per cent reactance inserted in the phase leads renders the third harmonic negligible; and even an 8 per cent reactance does all that is necessary in this direction.

REACTANCE AND REGULATION.

Increased reactance in a circuit with a lagging power factor naturally adversely affects the regulation. But this is a matter which is not so important as it was some years ago. In the past, specifications demanding good regulation have compelled the designer to force his designs and to produce a more costly machine. It has often been pointed out that good regulation is not an unmixed blessing, and that it is a big strain on the switchgear and the generator itself at the moment of short-circuit. Now, however, the situation is greatly changed. The development of the automatic regulator offers a solution, and a generator with poor inherent regulation can be made to give a pressure curve comparing favourably with the best that can be obtained from the most carefully designed good-regulating machine.

In a sense reactance improves the regulation, since at critical moments in the case of a short-circuit it helps to maintain the voltage when otherwise the pressure would have decreased and the synchronous machinery have fallen out of step.

REACTANCE IN TRANSFORMERS.

At first sight it might appear that the benefits conferred by reactance and reactance coils upon a generator should naturally apply, if not in degree at least in kind, to the transformer. This is, however, far from being the case, as the position is entirely different, and the premises which permit a successful application of reactance coils to the generator have little in common with those where such coils have to be considered for protecting transformers.

The problem of protecting a transformer against high-frequency surges is an old one. It has been found, as everybody knows, that these discharges flowing into the transformer break like a wave against a breakwater and expend their energy in the first few turns of the transformer winding, occasionally breaking it down. Reinforcing the insulation of the end turns has been successfully resorted to, but one would naturally inquire whether it would not be better to provide an external reactance coil to resist the on-coming wave. There can be no doubt that a special coil is more suited for the purpose, but it appears to introduce a concomitant source of danger which cannot be passed over without consideration.

A transformer possesses distributed capacity, inductance, and all the characteristics that go to form an oscillatory discharge; and not only would the reactance coil prevent abnormal waves from entering the transformer, but it would retain inside the latter all those oscillatory currents which either arise inside the transformer or come from the line, and are transformed to a higher pressure at the

² *Proceedings of the American Institute of Electrical Engineers*, vol. 31, p. 867, 1912.

point where the line is connected to the transformer. To remove all danger when using a large reactance coil it would be desirable to equip the transformer with a protective device across its terminals which would safely dissipate the oscillatory pressures. It would appear then that if the same protective effect of a coil could be secured by endowing the transformer with high internal reactance the latter method would be preferable. This point will be further discussed.

Up to recent years consulting engineers specified transformers with low reactance. They were in some way justified, for reactance was undesirable in a lighting circuit, but transformers for power purposes seldom escaped the same condition. Now, however, the position is reversed, and consulting engineers specify high reactance and obtain it. The interior of a transformer is, however, no place for a large amount of reactance. The duty of the transformer is to transform, and while the small percentage of reactance that may be desirable for the voltage regulation of not too greatly over-compounded rotary converters can usefully be embodied in the design of the transformer, the use of high internal reactance is undesirable. It may fail to achieve its object in one essential effect, and perhaps in two. In addition the eddy-current losses become largely increased.

The general idea underlying the choice of a high reactance in a transformer is that it will do two things:—First, it will limit the short-circuit current; and second, by this limitation the internal mechanical stresses of the transformer will be reduced. It may be that neither of these objects are attained to the desired degree.

There are many methods of increasing the reactance of a transformer, either by an adjustment of the design without the designer going out of his way to include any special feature, or by introducing a special leakage path. A small amount of reactance can be secured in a transformer of standard design sufficient for most rotary converter work, and higher reactances up to 25 per cent are possible by introducing special arrangements, such as the use of magnetic shunts to increase the leakage flux. But where this high reactance obtained by magnetic shunts is inserted merely to minimize the destructive tendencies of the short-circuit current, then the transformer is not protected as it might be, since it is impossible to design a transformer with magnetic shunts which will maintain its reactance in the case of a heavy short-circuit current. Far too much iron would be necessary in the shunt to carry the very heavy flux, and the regulation at normal loads would be very bad.

In the internal reactance no iron at all is of course used, an air core being employed in order to avoid this defect, so that high internal reactance may be useless for limiting the short-circuit current. Indeed, it is very doubtful whether most transformers would survive a "dead" short-circuit on their terminals if the full primary pressure were maintained, particularly if the short-circuit occurred at the moment when voltage was passing through its zero value, the flux then being a maximum. Cable breakdowns would occur at maximum voltage, so that stresses would not be so severe in that case.

On short-circuit, transformers have the advantage that they are able to count upon some of the generator reactance, although the full synchronous reactance could not

take part in damping down the short-circuit current. The exact amount of this assistance depends upon the relation between the sizes of the generator and transformer.

Considering next the reduction of the mechanical stresses inside the transformer due to the use of high internal reactance, many consulting engineers have thought a high internal reactance meant that the internal mechanical forces would be low in the case of a short-circuit. Yet high reactance is no absolute criterion of the relative strength of the internal mechanical forces. Of two otherwise identical transformers, the one with the lower reactance may conceivably experience smaller mechanical stresses at the moment of short-circuit. Everything turns upon how the designer has obtained the high reactance which he desires. The easiest and most convenient method of obtaining a high reactance is to decrease the number of coil groups in the winding, the reactance varying inversely as the square of the number of these groups. But so does the mechanical stress,² and a detailed consideration of the question shows that the mechanical forces are not materially reduced. On the other hand, if the increased reactance be obtained by enlarging the distance between the secondary and primary groups—and it will be noted that a high-tension transformer has inherently a higher reactance than a low pressure one owing to the larger amount of insulation necessary giving a leakage path of larger area—then high reactance is attained which will have the same effect as an external reactance coil.

Reactance can only be relied on as a current-limiting factor so long as the iron paths which carry the leakage flux remain unsaturated; high internal reactance does not improve the transformer—very often it will mean much greater eddy current losses—and there are a large number of transformer designers who would prefer to design their plant untrammelled by any need of attaining high reactance.

Summing up the merits and demerits of high internal reactance, it seems better to obtain any large amount by the aid of external coils, especially when the limiting of the short-circuit current is in mind. The risk of internal disorders may be considered remote or immediate, and if the latter view be accepted, steps would be taken to protect the transformer by a shunted discharger. Small reactance coils are usually immersed in the oil with the transformer.

REACTANCE COILS AND TRANSMISSION LINES.

Inductance plays a prominent part in the characteristics of transmission lines. In long lines, the line inductance is co-responsible with the capacity for a large rise in pressure towards the receiving end of the line. Any load other than one with a leading current reduces this excess pressure considerably—an inductive load more than a non-inductive load—and the power factor alters throughout the line. With an inductive load and a leading power

* The reactance is calculated from a formula of the nature—

Reactance volts

$$= \frac{(\text{no. of turns})^2 \times \text{current} \times (\text{area of leakage path})}{(\text{length of leakage path}) \times (\text{no. of groups})^2} \times \text{constant.}$$

while the formula for the mechanical stresses takes the form (where all the groups are alike)—

Mechanical stress

$$= \frac{(\text{no. of turns})^2 \times (\text{current})^2}{(\text{length of leakage path})^2 \times (\text{no. of groups})^2} \times \text{constant.}$$

factor at the generating end of the line, the power factor increases towards the end of the line, reaching unity at some point prior to the end. It then falls to a lagging value at the load.

This excess pressure is a cause of anxiety in long lines, for the voltage regulation is bad. On switching in the line the pressure at the far end rises at least to its no-load value, which may often be 150 per cent of the generator pressure. This will occur apart from any surges, but frequently the no-load voltage will be exceeded and a pressure 200 per cent of that of the generator may be reached. The immediate effect of such a rise in pressure is that the insulators at the far end of the line become over-stressed and may flash over. But the suspension insulator may be the strongest part of a system, so that the transformers will often be the first to break down if a failure occurs. By reducing the diameter of the conductor near the receiving end so that it is just above the critical value for corona loss for the maximum working pressure, the corona loss may be relied upon to relieve to some extent the over-tension of the line should the latter suddenly be deprived of its load. With varying loads, too, the pressure changes are great at the end of the line and are a considerable source of inconvenience.

To this difficulty has to be added that due to supplying the charging current to the line. At no-load this current often exceeds the kilovolt-ampere capacity of a single generator (say one-fifth of the total output of the station) with the result that two or more generators are kept running merely to supply a very small load. The remedy is simple, though it is doubtful whether it has yet been applied. Shunted capacity can be compensated for by shunted inductance,* and the best palliative would be a uniformly distributed inductance throughout the whole length of the line. This, however, is a counsel of perfection, and the best that financial considerations would permit would be a few reactance coils at intervals along the line. Preferably these should be automatically adjustable with the load, by methods discussed elsewhere in this paper, but non-adjustable coils would still serve. Except under special circumstances the power station is no place for these coils. By placing them along the line both the pressure rise and the heavy leading current are affected; but by putting them in the power station only the leading current is remedied, and then merely at the generator.

Apart from voltage regulation the introduction of reactance, series or shunted, may be used to increase the efficiency of the line and the maximum amount of power that can be transmitted.

A line with large inductance may take less power under short-circuit than on full load; indeed, this is a characteristic of the long-distance transmission line.

In transmission lines the conditions which prevent the use of iron in reactance coils for power-limiting purposes are not present. Iron-cored coils would be much cheaper and would lend themselves to several methods of automatic or hand adjustment which would not be open to coils with air cores.

The relations between the inductance and capacity, which play so prominent a part in shaping the transient

phenomena occurring in transmission lines, are not discussed in this paper.

CONSTANT POTENTIAL TRANSMISSION.

One of the developments that the future may hold is that of a large electrical network interlinked throughout and fed at numerous points at which opportunities for cheap power development present themselves. Such a system exists to some extent to-day on the north-east coast, and there is every likelihood that in other industrial centres this lead may be followed. In such a scheme under present conditions variations in pressure throughout the system are unavoidable. No matter how carefully the pressure-drops are calculated for the various portions of the network, calculations will be upset by inevitable temporary changes in the points at which the power is fed into the mains.

Voltage reduction is not a question to be treated lightly. Where it is recognized as inevitable, compensation can be effected in the ratio of the transformers supplying the load, but this means that transformers of varying ratio will be required all over the system; and even then where long distances are involved the difference of pressure between full and no-load will be large, the pressure of the generating station being supplied by shorter lines with practically no drop.

These and other considerations have given rise to proposals for constant-pressure schemes in which, however large and however extensive they may be, the voltage is maintained constant. The theory on which these proposals have been based is that since a leading current flowing through a reactance experiences a rise in pressure, this phenomenon can be utilized to give a constant-potential line by varying the amount of leading current according to the load. This theory, be it noted, premises the inclusion of a considerable reactance—no matter how it may have been obtained—in the line. The source of leading current of adjustable value can only be synchronous condensers, over-excited motor-generators, and (but not advisedly) rotary converters situated at various points about the system. That the current may be caused to flow in such a system from a point of lower to one of higher potential is no contravention of Ohm's law; for, of course, effective r.m.s. values are referred to. At any instant current can only flow from a point of high to one of low potential. Nevertheless, the r.m.s. value of the potential at the receiving end may be larger than the r.m.s. value of the potential at the power station owing to phase difference.

Constant-potential transmission calls for a large amount of reactance in the line contrary to orthodox practice, where reactance is avoided as productive of pressure drop. Most lines would not possess sufficient reactance, and therefore it would become necessary to add it in the form of series reactance coils. In addition, a frequency of 50 cycles would be preferable to one of 25, since it gives a greater reactance.

A system designed on these principles would have a number of remarkable operating characteristics. In the first place it would of course be the duty of the operating staff or of the automatic regulators to keep the voltage at any point constant by adjusting the leading current taken from the line by the synchronous condensers situated at

* In telephone work shunted capacity is compensated by series inductance (loading coils).

the various points. When a short-circuit occurred in any part of the line, in view of the fact that the short-circuit power would be less than the full-load power, there would be no general interference with the system. This is due to the fact that the short-circuit power would be limited by the reactance of the line—the reactance coils, if any, would be inserted at the generating end of the feeders—while for the load current the reactance is compensated by the leading current.

Faults would therefore be only local affairs, and since the reactance of the line, whether inherent or added, would have the effect of limiting the short-circuit current, the duty imposed upon the switches would be far less than in a scheme of orthodox design where the flow of energy is unlimited.*

The addition of line reactance together with the introduction of reactive power would appear at first sight to occasion an increased line loss. There is, however, no diminution of efficiency, since owing to the higher voltage the same work can be done with a smaller number of amperes.

REACTANCE COILS FOR THE PROTECTION OF MOTOR END-TURNS.

In some instances reactance coils are used to protect the end-turns of high-tension induction motors at the moment of switching on. These coils are often of the ironless pattern, a few turns of copper strip wound in a helix or flat spiral serving the purpose. Coils with iron cores are occasionally used, the three phases being wound on a common laminated straight core. It is imperative in such cases that the greatest care should be taken to insulate the coils well.

ADJUSTABLE REACTANCE COILS.

The problem of larger adjustable coils is one that will have seriously to be tackled in the future. It presents itself in its most acute aspect in the design of coils for shunting a transmission line; and the mode of adjustment which is found most satisfactory in this instance is to change the magnetic conditions. A continuous-current coil for superposing a continuous flux on an alternating flux might well be used to render the reactance coil adjustable. Without materially affecting the core loss the continuous current gives the iron a magnetic bias, and the reactance coil takes a higher magnetizing current than it would otherwise do. While this method was originally proposed for converting a transformer into a reactance coil, the author does not believe that the potentialities of this method of rendering reactance coils adjustable has yet been realized; at least, he knows of no suggestions which apply to such a method.

CONSTRUCTION OF REACTANCE COILS.

The construction of current-limiting reactance coils brings the designer face to face with a number of difficulties, the exact value of which it is not always easy to appraise. In addition to the severe mechanical stresses incidental to a short-circuit there are electrical stresses due

to transient voltages, the precise value of which cannot be foretold. Not only have the reactance coils to limit the current, but they have to carry the current until the short-circuit is cleared; and since with reactance coils the overload relays, if any, will be set high, it may be that the reactance coils will be called upon to carry the current for many minutes.

Owing to the circumstances under which the coils work, iron must be avoided in the construction, while in view of the strong leakage field, all solid metal-work in the coil will be a source of eddy currents and may become unduly heated and cause a fire. Steel bolts, for instance, must not be used.

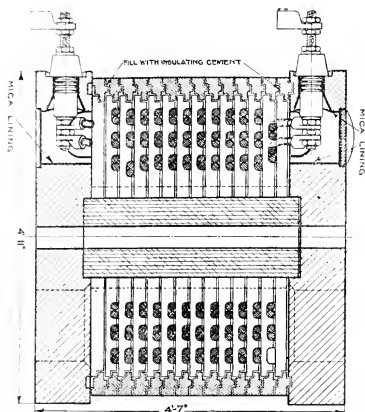

An 8 per cent reactance coil for a 10,000-kw. 6,600-volt generator would on full load have a pressure drop of 300 volts. A short-circuit on the generator busbar leads would result in a pressure of 3,800 volts, *i.e.* nearly 13 times full-load pressure, across the coil. Under such circumstances the reactance coil must still retain to the full its power to limit the current, and in order to meet this condition its magnetic circuit must not become saturated. In a reactance coil designed on orthodox lines, during short-circuit the magnetomotive force would be so great as to reduce the permeability of the iron to practically that of air. To enable the iron to remain unsaturated under this overload would mean such a low normal flux density that the use of iron becomes far from economical even if other electrical circumstances made it permissible. For this reason ironless reactance coils are the rule.

During short-circuit a large magnetomotive force is developed in these coils. In an 8 per cent reactance coil protecting a 10,000-kw. 6,600-volt generator there might be 44 turns. With full-load current the magnetomotive force is 38,000 ampere-turns, rising to 570,000 ampere-turns on a short-circuit current of 15 times full load. This is a large amount and calls for a careful disposition of any solid conducting material inside the coil.

In practice the coil takes several forms. In one, copper cable is wound under tension upon special wood supports which are bolted to a cylindrical concrete core. Where a single cable to give the requisite capacity would be too unwieldy, two are wound in parallel. According to its size the coil has three or five layers. The cables are quite bare, air being the insulator between adjacent turns. In view of the rise of pressure which must inevitably occur at the end-turns, each two end-turns are given greater clearance. Between each section or layer there is a space of several inches. Each end-turn is rigidly held by alloy clamps to the wooden supports. These supports are composed of strips of selected resin-filled maple having a disruptive strength of over 75 kilovolts per inch across the grain, and 30 kilovolts per inch along the grain. They are secured at their ends to the concrete core by radial brass bolts. Grooves are cut in the supports to receive the cable, which does not make direct contact with the wood. The copper and wood are separated by heat shields of asbestos. To increase the leakage distance between the layers of the winding and between the winding and the core, maple barriers are dovetailed into the sides of the supports. The supports themselves are not directly in contact with the concrete core, an insulating sheet separating the two.

* It is probable that switches will in the future be rated not alone on the capacity of the generator or feeder that they control, but upon the value of the short-circuit current—as limited by the reactance in circuit—which they are called upon to break.

The woodwork is finished with several coats of cream-coloured insulating enamel.

Sectional View of a Porcelain-clad Reactance Coil.

The core, which is hollow, is composed of a special mixture of cement, made by pouring into a collapsible iron mould. After removal from the mould the surface is levelled up and rubbed down, and is finally painted

externally and internally with a number of coats of light yellow creosote paint. To take the external mountings and bracings the end of the core is provided with hexagonal or square extensions, while for lifting purposes a large nut or washer is received by a cored recess. For clamping the wood supports to the core, cast alloy sockets are embedded in the surface of the core. Into these sockets pass radial brass studs insulated by micanite. The nuts on these studs are insulated from the wood by heavy insulating washers.

A further form of reactance coil is the porcelain-clad coil, the chief characteristics of which are that the pancake instead of the drum winding is adopted. The cable is enclosed in a porcelain case, with the result that the coil is smaller than one with air insulation. The reactances are built up of horizontally-wound spirals (see diagram) supported in recesses formed in the porcelain arms which radiate from a central core of alberene stone to an outer enclosing well built up of porcelain segments. There are two heavy concrete headers, one at either end, and these are fastened to the wall by a number of mica-insulated brass rods passing through the headers and porcelain segments. The conductors are insulated and the arrangement of the interior of the coil gives a cellular construction which permits adequate self-ventilation.

A typical coil constructed on this principle was said by the manufacturer to give the following results :—

- Number of turns, 34 ;
- Reactance, 4·2 per cent (20,000 kw. 6,600 volts
25 cycles) ;
- Ohmic resistance, 0·00195 ohm ;
- I² R loss, 6·05 kw. ;
- Eddy current loss, 0·186 kw. ;
- Total losses, 6·236 kw. per coil ;
- Temperature rise, 33° C.

ELECTRIC TRAIN-LIGHTING SYSTEMS.

By T. FERGUSON, Associate Member.

(Paper received 11th December, 1913; read before the MANCHESTER LOCAL SECTION 27th January, and before the BIRMINGHAM LOCAL SECTION 28th January, 1914.)

Although many papers have been written on this subject, which is in itself of somewhat limited scope, the author in this paper proposes to discuss the problems which have to be solved in order to meet the requirements of service from the Railway Traffic Department's point of view; then briefly to outline the general schemes of regulation commonly employed, and finally to describe some of the more interesting types of train-lighting systems, making special reference to the particular methods adopted for overcoming the difficulties presented by the exigencies of service conditions.

It must be admitted that the railways in the United Kingdom have certainly made considerable progress in many ways during the last 20 years, but it cannot be said that they have perfected any system for the complete prevention of collisions. Terrible accidents of this nature still occur from time to time, often resulting in disastrous fires, thus intensifying the suffering and adding to the death-roll. Much has been said and written with respect to the comparative danger and safety of gas and electricity as a means of train lighting, and it has even been denied that gas adds materially to the fire danger in case of collision, but the fact remains that in nearly every case of fire after a collision on steam railways, gas has been used for lighting the carriages.

It is interesting to note that quite recently Major Pringle in his official report on the Aisgill disaster says:—

"As regards illumination, I wish again strongly to urge upon railway companies the desirability of employing electricity as their standard illumination. It cannot be expected that all the gas-lighted vehicles can be replaced at once. The expense would be too considerable. But the policy of constructing all new stock with electric lighting and of replacing as early as possible the existing gas-lighted stock on main line and express services is in consonance with the trend of general practice all over the world, and one which is not impracticable from the point of view of expense."

The railways have been slow in adopting electric lighting for their passenger stock, but this reluctance to use electricity can hardly be for the reason that it is unsatisfactory as a means of illumination, or that there is no reliable system available, as there are many perfectly reliable electric-lighting systems on the market which sufficiently fulfil the requirements for ordinary working conditions. It would appear that the reason why electricity at the present date has not entirely superseded gas is one of capital expenditure.

When electric lighting was introduced on a commercial

scale some 20 years ago it found lighting by compressed oil-gas already in total possession of the field, except in some few instances where lighting by oil-lamps was still in vogue. The gas-lighting plant installed represented a very large capital invested in gas-works, compressing stations, travelling gas-tanks for charging the gas cylinders of trains in outlying districts, and also, of course, the storage cylinders and general installations on the carriages themselves. If all this were done away with and electric lighting took its place, obviously the cheapest system to use would be to install high-speed steam-driven generators on the locomotives and merely equip the carriages with lamps and wiring, providing suitable cable connections between the carriages. This would of course mean equipping all the locomotives and carriages on the railways, and also providing those goods wagons which are used with passenger trains with wiring connections and couplings. This system is used to a limited extent in America, where it is known as the "head end" system.

There are many variations of the straight "head end" system, usually embodying the use of storage batteries on one or more of the vehicles, together with the necessary regulating apparatus. The object of this is of course to maintain the supply of lighting at such times as the locomotive is uncoupled from the train or the generating plant is inoperative due to breakdown, low steam, or other cause.

The simple "head end" system, although certainly the cheapest in first cost and subsequent maintenance, affords some inconvenience to traffic working, inasmuch as the locomotives must remain attached to their trains for longer periods than are necessary with the gas-lighting system. Certainly a good deal of inconvenience in this respect could be overcome by providing the platforms of terminal stations with suitable lighting mains and plug connections to connect to the trains when they are standing alongside the platforms and waiting for their locomotives. There would still, however, be short periods when the locomotive with its generating set would not be available; for instance, when the trains are split up at junctions, and where very often several minutes are spent shunting different portions about the sidings. Suggestions have been made to equip such junctions with either collector rails or overhead wires connected to a lighting supply at the proper pressure, and so feed the carriage-lighting system through current collectors.

Besides the inconvenience of the "head end" system it does not lend itself to gradual conversion, and hence the lines upon which electric lighting systems have been developed are practically confined to the "individual unit" system, where each carriage carries its own

generator, driven from the axle, and also a storage battery to supply the lights when the train is standing.

There is an alternative course open in the case of block trains, and that is to light the complete train from one or more large axle-driven dynamos in the brake-van or vans, storage batteries and regulating gear of course being employed just as in the "individual unit" system.

The "individual unit" system is particularly well adapted to the requirements of the railways, as each coach so equipped is an independent unit, can be run anywhere on the railway, and has no storage tanks which require to be recharged at frequent intervals. The system can be introduced as gradually as required, the obvious way being to equip new coaches as they come out of the works and convert old gas-lighted rolling stock as opportunity arises. The capital cost of the system is of course much greater than that of the "head end" system, and the maintenance must also be considerably greater.

The author purposely refrains from giving any estimate of the cost of maintenance of electric lighting systems, as those alleged actual cost figures which have from time to time come to his notice have differed from each other so greatly as to make it more than doubtful whether any reliance can be placed on them. Then, again, so many of the railway companies use belt-slipping systems, and also in a great many cases double-battery equipments. Along with these are comparatively only a few of the more up-to-date single-battery systems, so that it becomes still more difficult to give any convincing estimate as to how economically the modern up-to-date single-battery systems may be maintained.

The author in this paper proposes to deal only with various examples of the "individual unit" system; but first of all he proposes to touch upon the problems which have to be solved, and then to describe some of the principal systems in the market, and how they meet the various difficulties.

In general it may be said that modern train-lighting equipments comprise the following apparatus:—

A dynamo slung from the underframe or truck frame of the carriage and belt-driven from a pulley on one of the axles. Means for regulating the voltage or output of the dynamo over a wide range of speed in both directions, and cutting it in and out of circuit at the right moment. A storage battery which is charged while running and supplies current to the lamps while the train is stopped or running slowly. Along with this is of course the necessary wiring, lamps, and fittings.

Traffic conditions demand that the equipments should answer the following requirements:—

1. The equipment may have to run on night service for long periods, hence the dynamo while running must generate more current than is required for the lamps, that is to say it must charge the battery while the lamps are burning, in order to make up for the current taken from the battery to supply the lamps while the train is stationary, and also to make up for the local losses which take place within the battery.

2. The equipment may similarly have to run on day service for long periods; hence some definite means for the adjustment of the output is necessary.

3. The same equipment may have to run on a suburban service having many stops and a low average speed, or an

express service with few stops and a high average speed. It would be a great drawback if the ratio of the pulleys had to be changed when passing from the one type of service to the other. On most railways the traffic department is not slow to raise objections if this has to be done. A train-lighting dynamo should be capable of operating satisfactorily between speeds of 12 and 72 miles per hour in order to make it sufficiently flexible in working.

4. Machines are required both for coaches requiring heavy and light lamp-loads, and as it is inadvisable to use many different sizes some form of output adjustment is again necessary.

5. The storage battery cells must be as few as possible, on account of first cost, subsequent maintenance, and "dead weight."

6. The equipment must be robust, simple, strong, obvious in action, and easy of definite adjustment, so that poor-class labour may be able to maintain it.

7. The maintenance cost must be as low as possible both as regards the dynamo and the batteries.

8. It should be possible to switch the lamps on and off at will without affecting the voltage applied to the lamps remaining burning.

9. The output must be easily and definitely adjustable to suit all conditions of traffic.

10. The additional draw-bar pull on the locomotive due to driving the dynamos must be as low as possible, especially at high speeds.

11. Batteries which have got into bad sulphated condition owing to coaches lying idle must quickly pick up again when the coaches are placed in service.

In order to study the problem of meeting the several requirements it is convenient to refer to a very elementary diagram of an equipment, such as that shown in Fig. 1,

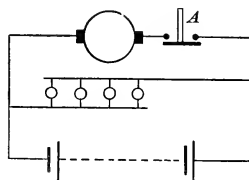

FIG. 1.

which represents the dynamo with its automatic switch A, storage battery, and lamps. As the usual pressure adopted is 24 volts, the battery will consist of 12 cells and will supply the lamps at a pressure of approximately 24 volts when the dynamo is stopped or running slowly. When the dynamo is running at sufficient speed to generate a pressure of 24 volts the switch A closes and the dynamo and battery are connected in parallel to feed the lamps. As the speed increases, the voltage of the dynamo will tend to rise and so take over the lamp load from the battery. At a certain point the battery will be merely floating and neither receive nor give out any current. As the dynamo voltage rises further, the battery will receive a charging current and the lamps will be over-run in volt-

age; a resistance must be inserted in the lamp circuit to absorb the extra voltage required for charging.

It is obvious that the dynamo may be regulated to give either constant current or constant voltage at speeds above the normal. In either case, if the battery is to be charged during lighting duty, the dynamo voltage must be considerably higher than the lamp voltage. In practice it should be at least 25 per cent above if the battery is to be kept in good condition. The difficult problem to be solved lies not so much in regulating the dynamo so that it gives constant current or constant voltage, but in dealing in the lamp circuit with the extra voltage necessary to charge the battery. Much effort has been concentrated on the problem of introducing and withdrawing in the lamp circuit compensating resistances in such a manner as to prevent fluctuations in the light.

It was this and other difficulties that early in the history of train lighting led to the adoption of the double-battery system diagrammatically represented in Fig. 2. The double-battery arrangement is practically

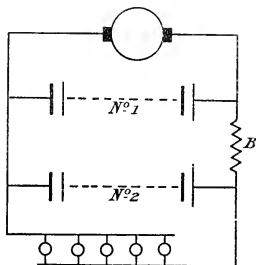

FIG. 2.

confined to constant-current systems, and the arrangement is that No. 1 battery is on charge while No. 2 battery supplies current to the lamps. The batteries are, however, connected by means of the resistance B, which permits the higher or charging voltage to send practically enough current through the resistance to supply the lamps, so that No. 2 battery should really float on the system. Any variation in the charging current will only alter the amount of current passing through the resistance, and No. 2 battery will have to supply more or less current to the lamps as the current from the dynamo rises or falls, as it may do owing to poor regulation, and certainly does do when the dynamo is switched into circuit and takes over the lamp current and battery-charging current, or vice versa.

It is obvious of course that when the voltage of No. 1 battery rises considerably, owing to the completion of the charge, or owing to a high rate of charging current, more current than the lamps require will flow through the resistance and No. 2 battery will begin to receive a small charging current, with a consequent rise of voltage on the lamps. It is also obvious that the effective storage

capacity of No. 1 and No. 2 batteries is not equal to the combined rated storage capacity of the two, as practically only one battery is receiving a charging current; and further, when the train is standing the two are connected in parallel, with the resistance B short-circuited, so that the fully charged battery will partially discharge into the empty battery, with consequent double losses.

The battery efficiency is therefore very low. A well-known firm of storage battery makers state that "with most double-battery systems the efficiency is probably not more than about 5 to 10 per cent of the current generated."

Even the double-battery arrangement is not very flexible in operation as regards compensating for voltage when lamps are switched off or on, as the resistance is only absolutely correct for a given condition of lamp-load and battery charge. If a considerable proportion of the lamps are switched off, the voltage at the lamps will increase.

The arrangement, however, is successful in maintaining a reasonably steady voltage on the lamps when switching the dynamo in or out of circuit, and also under fairly wide variations of dynamo current and lamp load. It is accordingly very much used as it enables a fairly steady light to be maintained with a comparatively poor dynamo regulation and with quite crude and simple automatic switchgear.

The double-battery arrangement is without doubt expensive to maintain, and also very heavy, as each battery of 12 cells for an ordinary carriage would along with its cupboard and hangers weigh about half a ton. A system which employs only one battery must be considerably cheaper to maintain and may be cheaper in first cost, as the value of the battery saved is equivalent to a considerable amount of extra regulating apparatus or switchgear.

It has been pointed out above that the dynamo may be regulated for either constant current or constant voltage, and systems are, broadly speaking, divided into two classes, viz. the "Constant Current" and the "Constant Voltage" systems. In the former the dynamo generates a steady current and its voltage is kept steady by the battery; in the latter system the dynamo maintains a constant voltage and the current output varies according to the state of the battery and the lamp load. Variations within these broad definitions may of course exist. For example, the dynamo may be regulated to give a constant charging current to the battery independent of the lamp load.

In the constant-voltage system the charging current to the battery falls off as the battery charge proceeds, so that overcharging is not usually obtained. Batteries, however, should be fairly often charged to the "gassing" point in order to keep them healthy, but a steady voltage high enough to "gas" the battery will give an excessive charging current at the commencement of the charge. It is accordingly much better to raise the charging voltage as charging proceeds. This may be done by using a resistance in series with the dynamo in constant-voltage systems, as it has the effect of raising the voltage at the battery terminals as the charging current diminishes, the increased voltage being, of course, due to the diminished drop in the resistance. With the constant-current system, however, this is what actually happens automatically, and the voltage on the lamps will vary to that extent.

In Figs. 3 and 4 charging curves are shown for constant voltage and constant current respectively. If the charging voltage is gradually raised as charging proceeds, a curve nearly similar to the constant-current charge of Fig. 4 is obtained. This curve shows the rise in voltage which takes place, and it will be seen that it is quite small over long periods, so that the variation in lamp voltage due to this cause will also be small.

In the author's opinion a constant charging voltage is not desirable, for the reasons given above. There is the

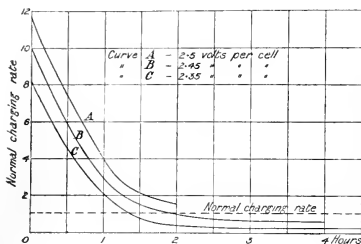

FIG. 3.

further disadvantage that a comparatively small variation in voltage will give a large difference in current. Fig. 3 shows the charging current curves for a battery at 2.35, 2.45, and 2.5 volts per cell. These curves show a high current charging-rate at first. If one cell in a 12-cell battery should become short-circuited, as sometimes happens, the current is considerably increased, since the battery is receiving too high a voltage per cell. On the other hand, a bad or dirty connection between the cells will reduce the current below what it ought to be for

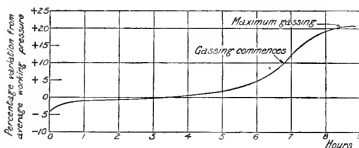

FIG. 4.

proper working. Further, a battery which has become badly sulphated, due possibly to a coach lying idle for a long time, will, on being put on charge, very rapidly increase in voltage, taking comparatively low current, even at first, and in a short time the current will have dropped to practically nothing, so that when the dynamo is stopped the battery has really got no charge worth speaking of, the result being that it goes from bad to worse.

It is in such points as these that the constant-current system has up to now proved the more practical system, and has been much more universally adopted than the constant-voltage system. With the constant-current system

the current need not be adjusted to within 10 or 15 per cent, as a variation to this extent—or even to a greater extent—will not appreciably affect the battery-charging voltage, and all that will happen is that the battery will take a longer or shorter time to charge. In the case of bad connections between the cells, or sulphated cells, the dynamo voltage will rise sufficiently to maintain the constant current, and the sulphates will become reduced and the battery charge maintained—it is true, of course, at the expense of a slight rise in voltage at the lamps, but this is better than crippling an expensive battery, especially at the present time when metal-filament lamps, which admit of wide temporary variations in voltage without real detriment to the lamps, are in universal use.

It will be further noted from the curve in Fig. 4 that when the battery becomes fully charged the voltage increases very rapidly. At this point it is advisable, although not absolutely necessary, to cut off the dynamo or at least reduce the rate of charging, and advantage may be taken of this quick increase in the voltage to operate some form of overcharge preventer system, examples of which are described later.

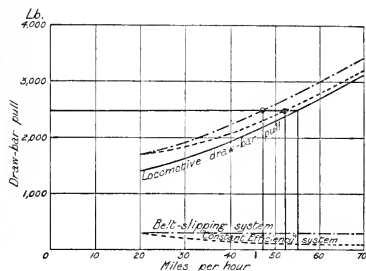

FIG. 5.

In connection with the subject of the extra draw-bar pull imposed on the locomotive by the use of electric train-lighting systems, it should be said that in both the constant-current and constant-voltage systems the draw-bar pull will decrease as the speed of the train increases. It should in fact be inversely proportional to the speed. Exception, however, must be taken to belt-slipping systems where the draw-bar pull remains constant, the power required to drive the dynamo being proportional to the speed, and the difference between this power and that required at the normal full-load speed being absorbed by the belt.

For any particular speed the constant-current system will offer the same draw-bar pull whether lamps are switched on or off and whatever is the state of the charge of the battery, until such time as the overcharge preventer may trip the dynamo out of circuit or reduce its output.

In the constant-voltage system the draw-bar pull will be high when the lamps are burning and the state of the battery is low, and will fall away as the battery charges up or the lamps are switched off.

Fig. 5 represents the draw-bar pull on level straight

track of a locomotive hauling 10 average coaches weighing altogether 300 tons (Armstrong). The extra draw-bar pull required by the dynamos for 8 coaches is also shown (2 coaches are assumed to be brake-vans without dynamos). By superimposing the added draw-bar pull on the train curve it will be seen that with a locomotive exerting a draw-bar pull of 2,500 lb. the speed of the train is reduced from 55 miles per hour to 52 miles per hour, or in the case of belt-slipping systems to 48 miles per hour. This curve is calculated for a total of 400 candle-power of metal-filament lamps per coach absorbing 1·25 watts per candle-power; this represents 21 amperes at 24 volts. Assuming the dynamo is giving 28 to 30 amperes at 30 volts (0·9 kw.) and taking the dynamo efficiency at 65 per cent, each coach requires 1·9 or, say, 2 h.p. to allow for belt transmission loss.

With most modern systems the efficiency at all speeds is practically constant; hence the draw-bar pull falls off as shown. However, with belt-slipping systems, as mentioned before, the draw-bar pull will be constant. In this case it is assumed that the dynamo is generating the above current at a speed of 20 miles per hour and above.

A study of the Patent Office records and of the literature on the subject will show that a large number of systems have been proposed, and many put on the market at one time or another. Some of these are as follows:—

Beaumont and Still.
Bliss (United States Light and Heat Company).
Buttner.
Brown Boveri (Old system—Aichelle).
Brown Boveri (New system).
Consolidated Light and Heat Company, U.S.A.
(several forms).
Gould-Simplex (U.S.A.).
Grob system (Pintsch Gas Lighting Company).
Leeds Forge Company.
Leitner-Lucas.
Moskowitz.
Mather & Platt (Rosenberg dynamo).
Newbold, U.S.A. (made by Adams Westlake Company).
"Safety" system (U.S.A.).
Siemens.
Silvertown system.
J. Stone & Co.
Tudor Accumulator Company.
Verity-Dalziel.
Dalziel's Improved Constant-voltage system.
Vickers-Hall.

Several of these have now practically dropped out of service, but there still remains a very fair number of systems from which the railway companies can make a choice. The author proposes, however, to describe and discuss only a very few of them.

STONE SYSTEM.

As Messrs. Stone & Co. are practically the pioneers of the "individual unit" system, it is natural to commence by reference to their system. This is so well known that a detailed description is hardly necessary, but a few general remarks may be of interest. The dynamo in the

Stone system is designed to work on the constant-current principle, and nearly all their equipments employ the double-battery system, whilst all the switches used for the automatic switch operation are controlled by means of a centrifugal governor contained under a dome cover fixed to the dynamo. The dynamo is in reality a torque-regulating machine, inasmuch as its output depends on the torque that the belt is able to transmit to the pulley by virtue of the frictional grip between them. The dynamo is hung pendulum fashion, and the belt is of such a length as to displace the centre of gravity of the dynamo from the vertical, and so keep a nearly constant tension on the belt. The voltage of the dynamo is determined by the battery, hence the current cannot increase above a definite amount, or the belt would slip. In other words the speed of the dynamo does not rise above full-load speed, however much higher is the speed at which the belt runs.

As the dynamo does not possess any other regulating device, it becomes a very cheap and simple machine, but obviously must possess the disadvantage of depending for its regulation entirely on the coefficient of friction existing at any particular time between the belt and the pulley. Hence the output will vary as the condition of the belt changes. For example, a new belt may be sticky on the surface and grip the pulley hard. In course of use, however, its surface will become glazed, and for a given belt tension the output would therefore be very different. Another disadvantage is that the dynamo inspectors cannot readily estimate what current the dynamo will give without making a run in the coach with a meter in circuit after any adjustment of the belt tension.

The waste of power at high speeds is also another serious drawback. If an equipment were geared to give its output at a reasonably low speed, say 15 miles per hour for a suburban service, the waste of power would be very great if the same equipment were run on express service without altering the pulley ratio. Taking for example a dynamo generating its full load of 30 amperes at 30 volts at a speed of 15 miles per hour, the horse-power input (assuming an efficiency of 67 per cent) would be 1·8 h.p. At 60 miles per hour the output is exactly the same, but the input is four times the above amount, namely 7·2 h.p. The extra waste of power absorbed by the belt is therefore 5·4 h.p., and the efficiency at that speed is therefore about 17 per cent. This is an excessive amount of power to absorb by the belt, and in order to save as much as possible wear and tear, and also the waste of power, it would be advisable to gear the dynamo for a lower speed ratio for express service, say to make it give full load from about 25 to 30 miles per hour for this class of working, while for low-speed suburban service it could be geared to give full load at a lower speed.

The question of the extra amount of coal burnt in the locomotive fire-boxes due to train-lighting equipments has exercised the minds of railway officials, with the result that more than one of the leading railways have made elaborate running tests with and without the dynamos coupled in order to ascertain the coal consumed for electric lighting. Generally speaking, in making coal-consumption tests it is found that there is a greater difference in the amounts of coal burnt for any two similar journeys than for similar journeys made with and without the dynamos coupled. In fact some journeys will show less coal burnt with dynamos.

running than without them. This may be understood when it is realized that the total horse-power required for the dynamos will generally average something like 5 per cent of the total power exerted by the locomotive, even with belt-slipping systems, and the total coal burnt may easily vary more than that percentage owing to differences in the direction and strength of the wind.

An easier and more accurate way of making estimates for the extra coal consumed by the dynamos is to test or estimate from the speed curves of the train the total dynamo output in kilowatt-hours, and from that deduce the amount of coal consumed. In a paper read before the Institution of Civil Engineers* an account was given of such a test. With some of the more modern systems the power consumption is naturally much less than with belt-slipping systems, hence the extra coal consumed becomes considerably reduced.

In spite of the disadvantages inherent to belt-slipping regulation, the system of Messrs. Stone & Co. has maintained its lead in face of severe competition from manufacturers of other systems, and this system undoubtedly operates satisfactorily. This is probably due to the fact that its action is quite obvious and easily understood; also that it is a constant-current system, and as such can be maintained by comparatively poor-class labour, since it does not require any particular nicety of adjustment.

LEEDS FORGE COMPANY'S SYSTEM.

The Leeds Forge Company's system is designed to avoid the disadvantages of belt-slipping regulation, whilst preserving its simplicity, robustness, and directness of action. The author is particularly interested in this system, having designed and developed it.

One of the main considerations in train lighting is low maintenance cost, and as storage batteries have about the highest rate of depreciation and maintenance of all electrical apparatus, it goes without saying that a system to be economical should be a single-battery system.

The Leeds Forge Company's system belongs to the "constant current" class, and accomplishes its regulation by means of the torque required to drive the armature. As the speed increases, the driving torque serves, by means of a cam, to thrust the armature bodily along its shaft in an axial direction from its normal position in the field, the thrust being resisted by a suitable spring. The armature with its commutator is mounted upon a sleeve which is free to slide on the driving shaft; and it is driven by a pin on the sleeve provided with a roller that works in a spiral cam-shaped groove cut in the shaft. This pin, when the shaft is rotating, bears against the side of the slot and so causes the armature to rotate with the shaft.

The power required to drive the dynamo cannot alter, as the pin has a tendency to ride along the slot; and since the shaft is fixed in its bearings this causes the armature to be pushed along the shaft out of the influence of the field magnet poles. This is done against the force of the regulating spring. As the speed increases, the armature is moved further out of the field; similarly as it decreases the armature moves back into the field. The spring is provided with an adjusting nut, so that the output can be

varied by altering the initial compression of the spring, and an output scale is provided marked in amperes, so that the dynamo attendant can readily adjust the output to a definite figure.

The slot in the sleeve is cut in both directions, so that the action is exactly the same in whichever direction the dynamo runs. The change in polarity is taken care of by fixing the brushes on a brush-rocker disc, which is mounted on bearings attached to the rotating part.

Regulation by withdrawal of the armature from the field enables a very wide range of speed variation to be obtained with a minimum of sparking and with a maximum stability of the field, as the ratio of the field-magnet ampere-turns to the armature ampere-turns, instead of becoming lower when the speed increases as in the case of regulation by weakening the field, in effect increases, because the magnetomotive force at the air-gap increases when the armature is thrust out of the field, owing to the diminished drop of magnetomotive force in the iron circuit.

In addition to this, the lead of the brushes is automatically increased with the speed. This is very simply accomplished by making the fixed stop for the brush-rocker reversing gear tapered instead of parallel, so that when the armature slides out of the field the brush-rocker is advanced. The range of speed obtained is very wide; the dynamo comes into action at about 450 revs. per min. and runs as a self-regulating machine up to its maximum safe speed. This limit is 3,000 revs. per min., although the dynamo would regulate beyond this speed. Assuming 42-in. carriage wheels and a pulley ratio of 5 to 1, a variation in speed of 11½ to 75 revs. per min. is obtainable, hence a carriage can be used indiscriminately for slow or express trains without changing the pulleys and without waste of power. The action of the machine is obvious and the adjustment of output easy, so that the system is adapted to be easily maintained by unskilled labour.

The automatic switchgear for switching the dynamo in and out of circuit and for introducing the voltage compensation into the lamp circuit when the battery is charging while the lamps are burning, consists of two solenoid switches with resistances. A complete diagram of connections for the system, including the windings of the solenoids, is shown in Fig. 6.

One switch controls the dynamo and the other the lamp circuits. The "dynamo" switch merely serves to connect and disconnect the dynamo from the battery and lamps when the dynamo voltage reaches or falls below the battery pressure. It is of the usual type with shunt and series windings and requires no further description except to mention that in its "down" position it short-circuits the series winding of the "lamps" solenoid.

The "lamps" solenoid switch, however, possesses several novel features with regard to regulating the pressure on the lamps. When the dynamo is stopped, the dynamo switch is open and the lamps receive current direct from the battery, the resistance 7-1 being bridged over. After the dynamo starts running, the dynamo switch closes at the right voltage and then the dynamo begins to take over the lamp current and relieves the battery. When its voltage has risen high enough to charge the battery, then—and only then—is the bridge over the resistance removed in steps and the

* R. T. SMITH. "Electric Lighting of Railway-Trains: the Brake-Vehicle Method." *Minutes of Proceedings of the Institution of Civil Engineers*, vol. 187, p. 142, 1911-12.

balancing connection 7-8 established via the main switch. The lamps are then connected across 10 cells receiving the charging voltage, so that the resistance 7-1 need not be altered when lamps are switched in or out. This saves a lot of complication of wiring and resistances when arranging the carriage lighting with individual lamps, each on its own switch. When the normal number of lamps is burning the I R drop in the resistance balances the charging E.M.F. of 2 cells and no current flows in the balancing wire. If more lamps are switched on, the difference in current between the normal lamp current and the new lamp current will flow along the balancing wire. The net result is—so far as the lamps are concerned—that their voltage is practically unaffected by switching lamps in or out; and, as regards the battery, the two end cells will either receive a little more or a little less charging current

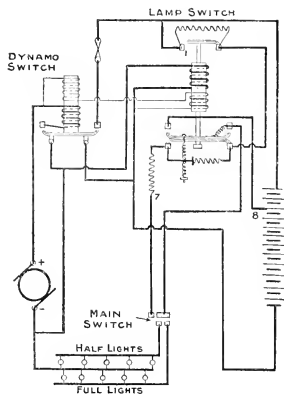

Fig. 6.

than the remainder, depending on whether more or less lamps than the normal are switched on. In practice this arrangement works very well and the end cells do not appear to suffer any inconvenience even after several years' service.

It will be seen from Fig. 6 that the lamps solenoid is provided with series and shunt windings, the series winding being in the battery circuit only. A current which charges the battery flows through this coil to assist the shunt winding, while a discharge current from the battery to supply the lamps acts in opposition to the shunt. Therefore until the voltage of the dynamo is high enough to supply a charging current to the dynamo the solenoid switch remains down. When the dynamo, besides feeding the lamps, begins to supply current to charge the battery, the series coil acting in conjunction with the shunt, lifts the plunger until the stop A comes in contact with the lower switch bar.

The upper switch bar being lifted, the first step of resistance is inserted. When the charging current increases, the plunger will overcome the force of the spring, and owing to the position of the spring will tip up the switch bar across the left-hand bottom and the right-hand top contacts, thus inserting another resistance in series with the first. The leverage is now in favour of the spring, and the last step is therefore not made until the current has further increased. The switch bar is then tipped across the top contacts, inserting the last step of the resistance and establishing the balancing connector. With this novel arrangement of solenoid and spring the switching movements are effected by means of a single solenoid with a comparatively small travel. When the dynamo slows down below the minimum speed the charging current falls and the switch goes through its movements in the reverse order.

The best feature of any constant-current system is that it ensures the charging of the battery eventually to the "gassing" point, and thereby gets rid of any sulphates which may be formed on the surface of the plates. The objection is sometimes raised against it that it overcharges the battery. Admittedly it may under certain circumstances; moreover a too long continuance of a gassing charge will tend to scrub the surface of the plates and boil away the acid. It is, however, easy to avoid this by using the over-charge preventer referred to above. Most over-charge preventers consist of a relay switch connected across the battery, which acts at a certain predetermined voltage and either cuts the dynamo out of action altogether or reduces its output. The voltage for the overcharge cut-out is indicated in Fig. 4.

The Leeds Forge Company use a small solenoid switch to break the dynamo field, thereby causing the machine to stop generating and the dynamo switch to drop out. The winding of this solenoid switch is connected across the battery via a small and simple switch which breaks contact when the dynamo stops. In this way a very reliable action of the solenoid is obtained, and the device does not depend on any delicate adjustment for releasing voltage when the battery voltage falls, as the solenoid plunger having been pulled "home" remains there until its circuit is severed by the dynamo stopping. Lost motion is provided between the solenoid plunger and the switch bar, so that the opening of the field is decisive. A similar arrangement of the plunger and spring to that employed on the lamps solenoid may be used to discharge the field on breaking.

MATHER & PLATT SYSTEM.

Messrs. Mather & Platt also adopt what is practically a constant-current system and use Dr. Rosenberg's patented generator. They usually prefer to employ the double-battery method, although they state that under some circumstances they are prepared to use a single battery. A diagram of connections of the system is shown in Fig. 7.

Dr. Rosenberg's dynamo is well known and has been frequently described in connection with train lighting. A brief résumé of its action may, however, not be out of place here.

The armature is an ordinary continuous-current one, revolving in a bi-polar field. The ordinary brushes are short-circuited, and a pair of extra brushes placed on an

axis at right angles to that of the short-circuited brushes are used to supply the current. The field poles are large and are provided with a small shunt exciting winding, which is connected across the battery and establishes a flux passing through the armature vertically. Rotation of the armature in this field produces a current through it via the short-circuited brushes, called the "aid" brushes. This armature current produces at right angles to the primary

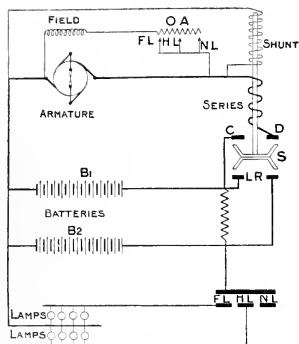

FIG. 7.

flux a secondary flux the path of which is through the pole shoes and the armature itself. The rotation of the armature in this secondary flux produces a difference of potential between the extra brushes, which are the main terminals of the dynamo. The component of the armature current which flows to the external circuit via these brushes produces a magnetomotive force opposing that of the shunt

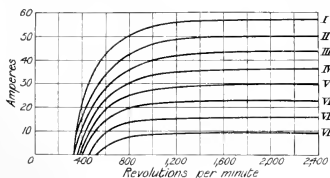

FIG. 8.

windings, and its value depends on the strength of the external current. This gives a similar effect to counter-compounding in an ordinary dynamo; but the effect is produced by means of the armature itself. The result is that with constant shunt excitation the current output curve will have the shape shown in Fig. 8. A number of different curves are shown in that figure corresponding to different values of the shunt excitation; and in Messrs.

Mather & Platt's system this adjustment of output is provided for by varying a resistance in the shunt-winding circuit. Usually the hand-operated main-lamp-circuit switch is arranged at the same time to vary the shunt resistance so as to reduce the output when the lamps are switched off.

The main point in the dynamo as regards train lighting is that it does not require any pole-changing mechanism in order to retain the same polarity at its terminals when its direction of rotation is reversed. The reason is that the shunt excitation remains in the same direction; hence the "aid" current will be reversed and so give the required working field in the necessary direction for maintaining the original polarity.

Messrs. Mather & Platt usually suspend the dynamo under the coach by links from the end sill of the bogie truck, the tension in the belt being obtained by an adjustable spring. The lamps are switched on and off by means of a barrel switch, which controls two lamp circuits, one being switched on for "half light" and the other added for "full light." At the same time the necessary switching of the shunt resistance is done in order to alter the output of the dynamo. The same barrel switch can also be made to interchange the batteries.

This system being a double-battery system takes care of the lamp voltage by means of the No. 2 or "floating" battery, in the manner referred to previously.

VICKERS SYSTEM.

Another example of constant-current operation is the latest system adopted by Messrs. Vickers, Limited. This is the "D.L." system of the Consolidated Lighting and Heat Company, U.S.A. The dynamo is a shunt-wound machine, and when the direction of motion of the carriage is reversed the correct polarity is maintained by means of a reversing brush rocker. The current is kept constant by means of a solenoid-operated automatic rheostat, the rheostat contact arrangement of which consists of a sector rolling on a flat track formed by the terminal studs that are connected to the resistance. The solenoid has one operating winding in series with the battery, and is provided with an adjustable diverter in order that the output of the dynamo may be adjusted. A single battery is used and the difference between the dynamo and lamp voltages is taken care of by another solenoid-operated automatic rheostat of a similar type to the first, except that the solenoid winding is a shunt winding connected across the lamps. An over-voltage relay is also used for preventing over-charge of the battery. When this relay acts, it switches current on to an extra shunt coil on the dynamo-regulating solenoid so as to assist the main winding and cut down the dynamo current. This system does not possess any particular features beyond those already mentioned, of using two separate regulators, one for controlling the dynamo and the other for controlling the lamp voltage.

TUDOR ACCUMULATOR COMPANY'S SYSTEM.

This is also a single-battery system on the constant-current principle. Regulation in this case, as in the Rosenberg dynamo, is accomplished by the windings of

the dynamo itself, and the characteristic output curve is very similar (see Figs. 8 and 9). The dynamo is reverse-compounded in the ordinary way, so that a separate pole-changing device is necessary. The series field-winding is provided with an adjustable diverter resistance.

The pole-changing arrangement adopted by the Tudor Company consists of a movable brush-rocker mounted on bearings on the shaft itself.

Both the Tudor Company and Messrs. Mather & Platt follow the same practice in varying the shunt-field excitation when the lamp-circuit hand switch is operated in order to alter the dynamo output as lamps are switched on or off. The Tudor Company's practice, however, in absorbing the difference between the dynamo and lamp voltages differs from that of Messrs. Mather & Platt. The former company employs special hot iron-wire resistances for this purpose, and these are permanently connected in series with the lamps.

The diagram of connections for the Tudor system is shown in Fig. 10. On this diagram are shown the automatic cut-in switch A, the overcharge preventer B, the

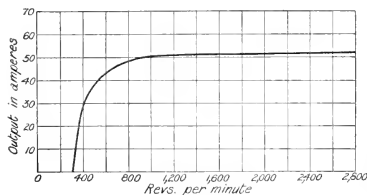

FIG. 9.

series diverter G, and the shunt-field resistances K, M, P, and R. The hot wire resistances for the lamps are also shown adjacent to the latter. The output of the dynamo is adjusted by means of the diverter on the series winding, this being necessary in order that the dynamo may accommodate itself to various conditions of service and lamp loads. The hot wire resistances absorb the difference of pressure between the dynamo and lamp circuits and also any variations in pressure that may occur on the system. These iron-wire resistances are enclosed in glass globes from which the air is excluded and hydrogen gas introduced, and they are run at practically a dull-red heat. At this temperature iron wire increases in resistance very rapidly with an increase of current, so that a considerable increase in voltage will make but little difference in the current passing through the resistance; hence the resistances act as a protection to the lamps. They possess, however, the disadvantage that they absorb a considerable amount of energy; in fact, the Tudor Company use a 15-cell battery to maintain 24-volt lighting, as against 12 cells used by other single-battery systems. This again requires a dynamo pressure of about 38 to 40 volts for charging the battery. Apart from the disadvantages of the extra maintenance involved by the additional storage cells and the special resistances and the losses therein, the use of hot wire resistances simplifies the problem of dealing with the difference between the dynamo and lamp voltages.

Prevention against overcharging the battery is taken care of in the usual way by a solenoid-operated switch, the windings of which are connected across the dynamo terminals. When the solenoid plunger is drawn up, on the charging voltage rising sufficiently, it increases the resistance in the shunt-field circuit and so cuts down the output of the dynamo. From the diagram it will be seen that the resistances are so connected with the overcharge preventer and the hand switch for the lamps that the shunt-field resistances inserted by the overcharge preventer are different when the lamps are on from what they are when

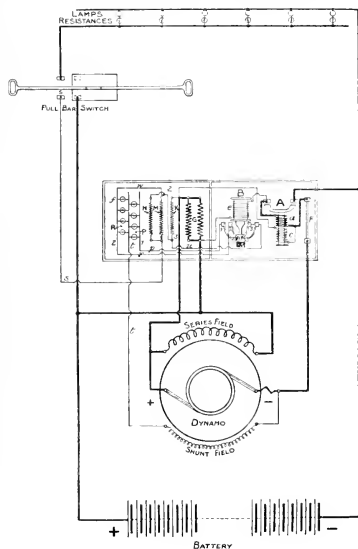

FIG. 10.

the lamps are off, as indicated in Fig. 10. It should be noted that the resistances P, R, are hot wire resistances in order to limit the shunt-field current to a given maximum.

On the Continent and elsewhere the Tudor and allied companies often use the Resenberg dynamo instead of a plain reverse-compounded machine. The remainder of the connections, however, are similar, and this system is sometimes referred to as the Buttner system.

SILVERTOWN SYSTEM.

This system is that of the India Rubber, Gutta Percha, and Telegraph Works Company, Limited. It is an ordinary double-battery system more or less similar to the

Stone system, except that regulation is not accomplished by the slipping of the belt, but by reverse-compounding coils, which carry the charging current to the battery. A series diverter is provided to adjust the output of the dynamo in the usual way. The switches are operated by a centrifugal governor.

The systems described up to this point have been examples of constant-current working, and certainly the majority of the existing systems operate on that principle. There are, however, several systems which use more or less the constant-voltage principle of operation. The best known of these are the Brown Boveri, the Dalziel, the Grob, and the L  tner.

BROWN-BOVERI SYSTEM.

Messrs. Brown, Boveri & Co. adapt their well-known voltage regulator for use with their train-lighting system. The main point in their arrangement is that they provide compound windings on their regulator, so that the battery charging-voltage is not held constant, but gradually rises as the battery becomes charged. By this means the battery charging-current does not have the characteristic of the purely constant-voltage system shown in Fig. 3, but more nearly approaches a constant-current

other relays is contained under one cover. The diagram of connections for the complete system is shown in Fig. 11.

The regulator R consists of a curved track composed of silver contact studs on which the sector-shaped contactor A rolls. The various sections of the field resistance are connected to the contact studs as shown in Fig. 11. The sector-shaped contactor is rolled over the studs by means of the moving coil O, which is capable of a partial

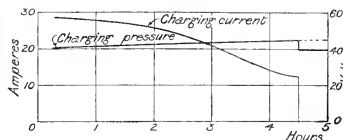

FIG. 12.

rotation between the field poles of an electromagnet with a shunt winding M_1 and series windings M_2 and M_3 . The movement of the coil O is opposed by the control spring F, which has an approximately constant tension over the working range of the moving coil. The moving coil is connected in series with the fine-wire magnet winding M_1 , the winding of the over-charge relay U, and the resistance H, the complete group being connected across the dynamo terminals. The winding P of the cut-in switch C is connected across the first two contact studs, so that when the dynamo is run up to normal speed and the voltage exceeds a predetermined minimum, the sector commences to roll away from its end position where it was short-circuiting the winding P. Hence, by the first movement of the sector the winding P is energized and the dynamo circuit to the battery is closed by the switch C. At the same time the direct circuit from the battery to the lamps through C is broken, and any lamp current required has now to go via series coil M_1 and lamp resistance J. If the lamps are not switched on, switch K remains open, leaving the coil M_2 active. If K were closed, the coil M_2 would be short-circuited. As the dynamo speed increases, the voltage tends to rise, but is prevented from doing so by the movement of the regulator introducing resistance G in steps into the field circuit. The current charging the battery passing through winding M_1 assists the shunt coils M_1 in moving the regulator, so that when the dynamo is running without the lamps switched on, the voltage necessary to move the regulator will be low when charging current is high, and vice versa; that is to say, as the battery charges up and its back E.M.F. increases, the current will fall, thereby in turn requiring a higher voltage of the dynamo, acting through the fine-wire windings of the regulator, to move the coil O. The battery is therefore charged on a rising voltage characteristic, which gives the charging-current curve shown in Fig. 12; this is similar to the charging-current from a constant-voltage supply main having a resistance in series. The charging will continue until the voltage builds up to the amount necessary to attract the armature of the magnet U, when the resistance H will be partially short-circuited. This

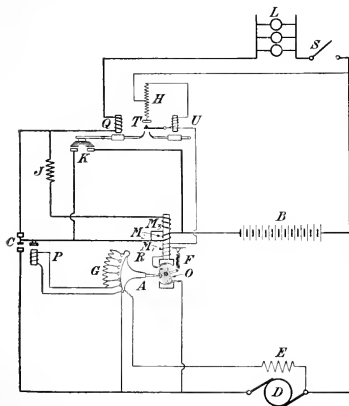

FIG. 11.

curve. A charging curve for the Brown-Boveri system is shown in Fig. 12.

The dynamo is an ordinary shunt-wound machine, the field excitation of which is controlled by the regulator. The pole-changing device in connection with the reversal of the direction of motion consists of a movable brush-rocker mounted on the end bracket and operated by a special arrangement of levers and springs. The regulator, together with the electrically-operated cut-in switches and

will cause the sector A to roll further over the resistance studs and the output of the dynamo to be decreased to a very few amperes.

Should, however, the lamps be switched on, current will flow through the resistance J and magnet Q; this will close the switch K and therefore short-circuit the battery winding M_1 . At the same time the lamp current will flow through the winding M_2 , which acts in opposition to the shunt-wire winding M_1 ; hence the greater the lamp current the higher must the dynamo voltage rise to balance the force of the control spring; and as the greater the lamp current the greater is the drop in the lamp resistance J, the two are proportional to each other and a steady pressure is maintained on the lamps.

In this way the lamps can be switched off and on with very little alteration in pressure; but in the author's opinion this arrangement is not good, as the larger the lamp-load the greater is the charging current of the battery, and a heavy lamp-load coming at a time when the battery is low may mean a very severe strain on the dynamo, as the compensating effect of M is absent, due to its being short-circuited by K.

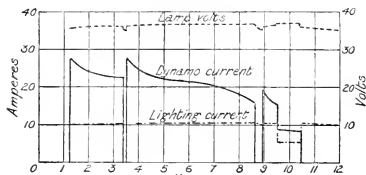

FIG. 13.

The performance curve showing the dynamo and lamp currents throughout a run lasting 12 hours is given in Fig. 13, and it will be noticed that when only half the number of lamps are in use the dynamo current is comparatively low, whereas when all the lamps are in use at the beginning of the charge the dynamo current is 2½ times the lamp current.

This system is obviously a step in the right direction, inasmuch as it raises the voltage on the battery as charging proceeds, and is in this respect a happy compromise between the pure constant-voltage and the constant-current systems. It is unfortunate, however, that the arrangement for taking care of the varying lamp pressure should partially interfere with this good feature.

DALZIEL SYSTEM.

In a paper read before this Institution some years ago²⁰ Mr. Dalziel described a constant-voltage system invented by him. Unfortunately, in order to obtain the desired regulation he had to employ in addition to the dynamo a system of motor-generator and exciter gear which made the complete arrangement rather complicated, as there were too many small armatures and commutators, brushes, etc., to be readily maintained. It is interesting to learn

that Mr. Dalziel has now reduced the auxiliary motor-generator system to a single exciter geared direct to the dynamo shaft. As the improved system supersedes the older one, it will only be necessary to refer to this later form.

The diagram of connections and the arrangement of the dynamo and exciter are clearly shown in Fig. 14. It will be seen that the magnetic circuit of the exciter is some-

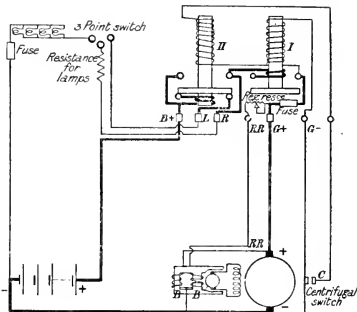

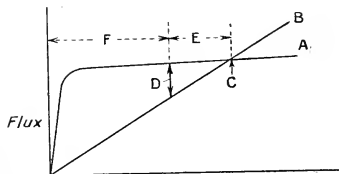

FIG. 14.

what unusual. The main generator field is connected across the armature of the exciter, which revolves in a field that is the resultant of the fluxes on the two poles B B. These poles are so wound and connected across the dynamo terminals that the magnetomotive forces produced are in series. The one pole is of small section and becomes saturated at a very low terminal pressure. The other pole is of large section, possesses a fairly long air-gap, and

M. M. F.

FIG. 15.

is very far from saturation, in fact, possesses nearly a straight line characteristic.

These two characteristics are shown in Fig. 15, where A is the curve for the saturated pole, and B the curve for the unsaturated pole with the air-gap. The difference between these two curves represents the flux passing through the exciter armature. Hence if D represents the difference in flux necessary to give the required excitation at the

²⁰ *Journal I.E.E.*, vol. 39, p. 156, 1907.

minimum normal or cut-in speed of the generator, the voltage cannot increase beyond the point represented by C, which is the point of "no flux" through the armature, corresponding to infinite speed; that is to say, the part E measured as a percentage of the part F is the percentage rise in the main voltage corresponding to a rise in speed from the cut-in point to infinite speed. By designing the exciter to give the necessary voltage with a sufficiently small flux, this percentage rise may be made as small as may be required. In order to keep the size of the exciter within reasonable limits, it is geared to run at a higher speed than the main generator.

The difference between the dynamo voltage and the lamp voltage is, as usual, absorbed by means of the lamp resistance. Each lamp or bank of lamps controlled by a separate switch is provided with its own resistance, and these resistances are "cut in" in one step. The dynamo is switched in parallel with the battery at the correct voltage by means of the usual solenoid switch 1, provided with series and shunt windings; but instead of switching it direct into circuit with the battery, it is switched in through the lamp resistance and the lamp switch. Assuming the latter to be closed, the path of the current is through G, switch 1, terminal R, the lamp resistance, the lamp switch, and back to terminal L, through solenoid switch 2, through the series holding coil of the same to the positive pole of the battery.

As the speed of the dynamo and its voltage increase, the dynamo takes over the lamp current, and the current in the series holding coil of solenoid 2 is reduced to zero, and this switch is free to act whenever its operating winding circuit is closed. Meanwhile this has been accomplished by means of the centrifugal switch C. The solenoid switch accordingly closes and so connects the dynamo direct to the battery, leaving the lamp resistance between the lamps and the dynamo. When the dynamo slows down, the reverse action takes place. This is where the necessity of the centrifugal switch C comes in, as it is impracticable to make solenoid 2 drop at the right moment without breaking its circuit by means of the centrifugal switch.

This system as illustrated in the diagram is a pure constant-voltage system, and the battery will be charged in accordance with the curve shown in Fig. 3. In the author's opinion, as already expressed, this is by no means the best way of treating the battery in practice, and it would be much better to insert a resistance between the positive terminal of the dynamo and terminal G and run the dynamo at a higher voltage in order to get the benefit of the diminishing drop in the resistance, with consequent building up of the voltage as the battery becomes charged. The lamps would of course be subjected to this amount of voltage variation; but as the lamp resistance would be designed accordingly, the variation on either side of the correct voltage is by no means serious.

As this system employs a separate exciter, driven from the dynamo, it does not require any further pole-changing apparatus, as the polarity of the exciter reverses when the direction of motion is changed, thus altering the direction of excitation of the main generator; which is just what is required to maintain correct polarity.

The author would like to suggest to Mr. Dalziel that instead of using a compound magnetic circuit for his

exciter he could merely use a standard exciter with two shunt windings connected across the main dynamo terminals. The two windings would act against each other, but in the circuit of one he could insert a hot iron-wire resistance. This would at once limit the excitation current in that winding. The working flux would be obtained from the difference between the two excitations, and the same effect is obtained as in his compound magnetic circuit, with possibly the advantage that it is not necessary to develop a fresh machine for the purpose. It would also be possible to use permanent magnets in place of the constant-excitation winding.

GROB SYSTEM.

In this system constant voltage is also used, but the dynamo runs at the same voltage as the lamps and the battery receives its charge through a booster. The booster armature and the main armature work in the same field, so that the same regulation applies to each. The Grob dynamo is arranged with its field coils in series with a regulating battery, the two being connected in series across the dynamo terminals, so that current from the battery would tend to drive the dynamo as a motor. When the dynamo, however, increases in speed it generates a counter electromotive force which gradually reduces the current and therefore the excitation; hence the dynamo voltage could never quite reach that of the battery, but from normal speed upwards it is just so much below it as is given by the varying I R drop in the coil.

A second battery connected across the dynamo and booster in series is of course required for charging. The two batteries are arranged to be interchanged at suitable intervals so as to prevent the regulating battery running down. The general idea of running the lamps direct from a dynamo, regulated to generate the lamp voltage, appears to be very good, but the complication and expense necessitated by the particular arrangement of regulation and charging is a considerable disadvantage, and the switching operations are also rather complicated.

CONCLUSION.

The systems described above deal with the problems of train-lighting in different ways, and the respective merits of each system are open to much discussion. A table is attached to this paper, in which is given a list of a number of systems, tabulated with reference to the various points discussed above. The constant-current and constant-voltage schemes each possess distinct merits. Judging from the examples at present on the market, it would appear that the constant-current system is by far the more popular; and most of those systems which use a constant voltage or some modification of constant voltage employ a rising characteristic for charging. Even if constant current represents the extreme of this rising voltage characteristic, yet its simplicity, ease of adjustment, independence of fine adjustment, and facility for de-sulphating faulty batteries, commend it to the practical railway-lighting engineer, who can feel some confidence that even should the regulation of the dynamo or special regulator become somewhat coarse through unavoidable defects or rough handling, the working of the system will not be very much impaired.

In the opinion of the author single-battery systems will have to be much more universally adopted in the future if electric train lighting is to make the progress that is expected of it, as by reducing the number of cells the maintenance and depreciation costs of the equipment are certainly decreased by 25 to 30 per cent.

In conclusion, the author wishes to thank Mr. J. Dalziel

of the Midland Railway, and also the following firms—Messrs. Brown, Boveri & Company, The Chloride Electrical Storage Company, The Leeds Forge Company, Messrs. Mather & Platt, The India Rubber, Gutta Percha, & Telegraph Works Company, and The Tudor Accumulator Company, for their kindness in giving him information.

‡ Pure constant-voltage system

§ Has one battery as regulator.

ON A VARIABLE CONDENSER WITH A SQUARE LAW.

By W. DUDELL, F.R.S., President.

(Paper received 1st December, 1913.)

Continuously variable condensers are in considerable use, especially in connection with wireless telegraphy. In using these condensers for the purpose of measurement it often happens that the quantity to be measured is proportional to the square root of the capacity of the condenser; for instance in wave-meters of the Donitz type, which consist of a fixed self-induction and a variable condenser, the condenser being set to resonance, the wavelength is approximately proportional to the square root of the capacity of the condenser.

For this reason it would be convenient in many cases if the capacity of the condenser were proportional to the square of the distance traversed by the moving part.

Rotating-sector condensers, consisting of a number of plates or sectors which move in and out between a number of fixed ones, are often used in wireless telegraph receivers. In this case the capacity, except near the extreme ends of the scale, is very nearly proportional to the angular displacement of the moving plates; in fact, in a well-constructed sector condenser if the capacity be plotted against the angle a straight line will be obtained except at the two extreme ends of the scale. This straight line does not, however, pass through the zero point. It generally passes through such a point that if a small number of degrees (say 4 or 5 in a good condenser) be added to the readings of the condenser then its capacity is strictly proportional to this quantity.

With condensers of this type used in resonating circuits it will be found that if the capacity of the condenser be chosen so as to be convenient for tuning at the lower end of its scale, then owing to the fact that the wave-length is proportional to the square root of the capacity, the longer wave-lengths at the top of the scale will be unduly separated, or if the wave-lengths are conveniently spaced at the top of the scale they are too closely crowded together at the bottom.

A number of experimenters have recognized the advantages, in certain cases, of what may be termed a square-law variable condenser; and various arrangements have been proposed and constructed to attain this result. In particular, Mr. C. Tissot* has proposed a condenser in which one set of lozenge-shaped plates (see Fig. 1) slide in and out of a corresponding set of similar-shaped plates.

It is evident that the same result can be obtained with the rotating-sector condenser provided the plates be given the correct curve. Probably a number of experimenters have already worked out the correct curve, but the author is unaware of where the results are published. The object of the present note is to put on record a curve which has been tried for the purpose, and the results obtained.

The problem is very similar to that worked out by Ayrton and Mather in the design of their electrostatic voltmeter, which is essentially a variable condenser hav-

ing a definite law in order to obtain the required scale. The main difference is that in the case of the electrostatic voltmeter the rate of change of the capacity with regard to the angle determines the scale, and the zero capacity is of minor importance; whereas for the square-law condenser the actual capacity is required to be proportional to the square of the angle, and the capacity at zero position must be as small as possible.

There are a number of possible combinations of curves which give the required results. We have two sets of plates to deal with; and in what follows it will be assumed that the moving plates are fixed to a spindle and are capable of rotation through an angle of approximately 180 degrees, and that during this rotation the moving plates enter between the fixed plates. It will also be assumed that the perpendicular distance between the

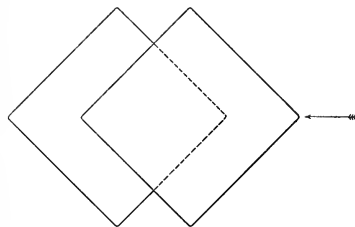

FIG. 1.

moving and the fixed plates is a constant, and in general small compared with the linear dimensions of the plates.

If this be the case, the capacity of the condenser is merely proportional to the area of the moving plates that are within the fixed ones, plus a small correction due to the edge effect which will be considered later. In its simplest form the problem is therefore to design the shape of the edges of the plates so that the area of the moving plate enclosed by the fixed plate is proportional to the square of the angle through which the moving plate is rotated. There are four possible simple cases:—

The inside bounding edge of the fixed plate may be a semicircle concentric with the spindle, and the outside edge of the fixed plate may be so large that the moving plate never projects beyond it, so that its shape need not be taken into account; combined with:—

(a) A moving plate which has its outside edge shaped to a suitable curve (see Fig. 2a).

(b) A moving plate, of which the outside edge is part of a circle concentric with the spindle and the inside edge part of a spiral curve (see Fig. 2b).

* *Journal de Physique*, vol. 2, p. 719, 1912.

The moving plates may have their outside edges parts of circles concentric with the spindles; combined with:—

(a) A fixed plate which has its inside edge constructed to a curve and the outside edge so large as not to have any effect (see Fig. 3a).

(b) A fixed plate, of which the inside edge is part of a circle and the outside edge is shaped to a curve (Fig. 3b).

There is no difficulty in working out curves which will approximately suit these four cases. There are also a

considerable length of the edges of the moving plates at a distance from the spindle and therefore nearer to the lining of the case. From the mechanical point of view the type shown in Fig. 2b is very unsatisfactory, as it is difficult to support the moving plates from the spindle and avoid possible risk of deformation. The type illustrated in Fig. 3a is mechanically satisfactory, but in that shown in Fig. 3b there is again the difficulty of inadequate support, this time of the fixed plates.

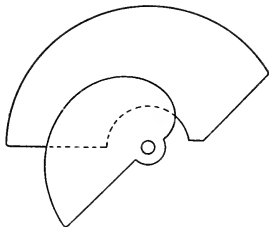

FIG. 2a

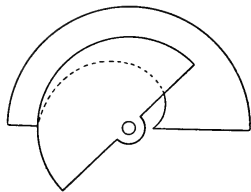

FIG. 3a

number of other cases where both the fixed and the moving plates have their edges cut to special curves, but there appears to be no special reason for their adoption, and they are certainly more complicated to make.

In choosing between the four types mentioned above, two considerations have guided the author to adopt the type shown in Fig. 2a. First, it is essential that the moving plates shall be mechanically strong; secondly,

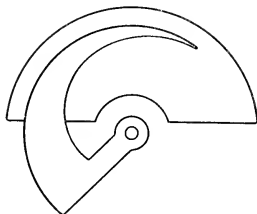

FIG. 2b

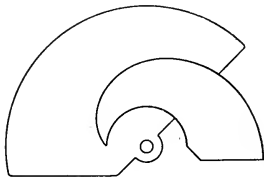

FIG. 3b.

the capacity of the condenser when the pointer is at zero must be made as small as possible. It is usual with sector condensers, in order to make the capacity perfectly definite at low values, to line the case with conducting material and to connect the fixed plates and the interior conducting surface of the condenser together. It is therefore necessary, in order to have a low zero capacity, that the moving plates should have as little outside surface and should be kept as far away from the case as possible.

In this respect the type shown in Fig. 2a is good, compared with the other three types, because the latter have a

The final choice has therefore to be made between the types illustrated in Figs. 2a and 3a. The curve for the edge required is practically the same in these two cases. In view of the fact that it seems easier to get a small zero capacity with the type in Fig. 2a than in that of Fig. 3a, the former was finally adopted.

The problem resolves itself into the following:—Let r (Fig. 4) be the radius of the inside edge of the fixed plates, x be one of the radii of the curve, and θ the angle through

which the moving plate is rotated from its zero position. The problem is to make the area abc , bounded between the curve and the circle of radius r , proportional to the square of the angle θ . This leads to the following formula for the curve:—

$$x^2 = 4k\theta + r^2,$$

where k is a constant such that the area $A = k\theta^2$.

In the actual condenser constructed the radius r was first taken at 2 cm. and $4k$ at $36/\pi$, the angles being measured in radians. In this case we have the area $A = 9/\pi\theta^2$ and the equation to the curve is $x^2 = 36/\pi\theta + 4$.

Or if θ is measured in degrees, by

$$x^2 = 0.2\theta + 4,$$

which is represented by the curve given in Fig. 2a.

The capacity of the condenser at any position θ may be easily calculated, since

$$\text{capacity in mfd.} = A/l \times 2\pi \times 8.86 \times 10^{-8},$$

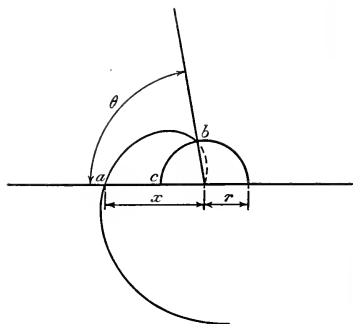

FIG. 4.

where A is the area of a plate in position θ ; l is the perpendicular distance between the plates, and n the number of moving plates—always assumed to be one less than the number of fixed plates.

The condenser as made consisted of 13 moving plates

and 14 fixed plates, the clearance between the moving plates and the fixed plates being approximately 1 mm. When finished, the condenser was tested and its curve plotted. It was found that the capacity was not strictly proportional to the square of the angle. A consideration of the edge effects which have so far been neglected shows that this might be expected. It also shows that an improvement can be made by increasing the radius r without altering the shape of the curve. The radius was therefore increased by 3 mm. and the condenser was re-tested.

The calibration curve of the condenser can be very closely represented by a formula of the form—

$$\text{capacity} = a + b\theta + c\theta^2,$$

in which the constants a, b, c , have the following values:—

Before increasing radius r :	After increasing radius r :
a 0.022	a 0.025
b 0.017	b 0.0035
c 0.0072	c 0.0059

where θ is measured in radians and the capacity in milli-microfarads.

It will be evident from the above figures that the increase of the radius has greatly improved the condenser and nearly made the term b negligible. Possibly a slightly greater increase would have further improved matters.

Although it has not been possible to get the initial capacity " a " as small as one would like, nevertheless the condenser has proved very convenient in use, and it is hoped that the above data may save some other experimenters from going through the work a second time.

THE THEORY OF THE THREE-PHASE SYNCHRONOUS MACHINE.

By T. F. WALL, D.Sc., M.Eng., Associate Member.

(Paper received 31st July, 1913.)

In a previous paper* I showed how the circle diagram for the induction motor may be deduced from a consideration of the rotating fields due to the three-phase currents in the stator and rotor windings respectively. It is here proposed to apply a similar method of treatment to the development of the circle diagram for the synchronous machine.

The circle diagram for synchronous machines has been discussed by many writers, notably by Arnold and La Cour,† who have made use of the idea of equivalent coils and the principle of inversion. In my opinion, however, the conception of equivalent coils and the principle of inversion are, for many people, too much of the nature of a mathematical abstraction, and the physical meaning is not easily grasped. I therefore hope that the method here described (which may conveniently be referred to as the rotating-field method) will allow the reader to keep in view the actual physical meaning of the steps of the

development. The accuracy obtained is the same as that given by other methods. I have obtained in a simple way many of the results deduced by Arnold and La Cour from the circle diagram; and it is hoped that this may bring the circle diagram and the deductions therefrom before a larger number of readers than has hitherto been the case.

The importance of the circle diagram for the synchronous machine lies in the fact that it enables us to obtain a comprehensive survey of how the ideal machine may be expected to behave under various conditions. In practice, however, the influence of the salient poles, and of the varying degrees of saturation of the magnetic circuit, is so considerable that the results obtained from the circle diagram can only be taken as a general guide.

It is here shown how the vector diagram may be drawn and the "V" curves deduced when the saturation of the iron and the fact that the poles are salient are taken into account. The results of tests are given, and a comparison is made between the test data and the results deduced by means of the vector diagram.

* *Journal I.E.E.*, vol. 48, p. 499, 1912.

† See E. ARNOLD "Die Wechselstromtechnik," vol. 4; also K. PICHELMAYER "Dynamobau," vol. 5.

is assumed to be negligibly small the mechanical power developed by the motor per phase will be $V I \cos \phi$, where ϕ is the angle between the current vector OA and the vector of the applied pressure OF. Hence the power developed by the motor will be proportional to AH, i.e. to the perpendicular distance of the extremity of the current vector from the abscissa axis. The abscissa axis may therefore be called the "Power Line." The machine being a synchronous machine the torque is also proportional to AH; hence the abscissa axis may be called the "Torque Line." The scale for the torque is given by—

$$\begin{aligned} \text{Volts per phase} \times \text{amperes (AH) per phase} \times \frac{746}{2 \pi \times r.p.m. \times \text{Torque (lb.-ft.)}} \\ = \frac{33,000}{33,000} \end{aligned}$$

For the lower half of the circle GA the torque will be negative; and this means that the machine will then be working as a generator. When the motor is developing a torque represented by AH, and the load is suddenly increased, the field-system NS (Fig. 1) will fall back, i.e. the angle θ in Fig. 1 will be increased and the point A will consequently move to some position A' until the torque developed is sufficient to overcome the increased retarding torque. Generally the point A will travel a little beyond this position of equilibrium because of the inertia of the moving parts, and it will oscillate and gradually settle down to the position for which the driving and retarding torques are equal, after the oscillations have died down. This effect, however, will not be considered further at this juncture.

The point A, gives the position of the current vector for the maximum torque obtainable with the given exciting current. If it be attempted further to increase the load, the point A moves beyond A, the driving torque of the motor decreases, and the machine falls out of step. The same considerations may be applied for the lower half of the circle, that is to say, for the generator, and the point A' will give the maximum output as a generator. The line A, A' will thus mark out the limits of stability of the machine, and the corresponding points on the pressure circle will be B, B'. For various values of the excitation a series of concentric circles will be obtained having centres at the points D and G respectively. The limits of stability will be given by the following relationship—

$$O B_1^2 = O D^2 + D B_1^2.$$

But OD is a constant, hence—

$$O B_1^2 - D B_1^2 = \text{a constant, namely } O D^2,$$

$$\therefore I^2 X^2 - E^2 = \text{the constant, } V^2,$$

that is—

$$I^2 - E^2 X^2 = \text{the constant, } V^2/X^2.$$

Hence if, for the limits of stability, the armature currents per phase be plotted as ordinates, and the corresponding values of the induced E.M.F.'s E as abscissae, the curve of stability limits so obtained will be a hyperbola, the apex of which will lie on the ordinate axis, at a distance V/X from the origin.

Again, if we suppose that the excitation is so adjusted

that the value of the power factor is kept equal to unity as the load varies, then the current vector will always coincide with the ordinate axis. The following relationship will therefore hold:—

$$G Q^2 = O Q^2 + G O^2,$$

that is—

$$G Q^2 - O Q^2 = G O^2,$$

or—

$$E^2/X^2 - I^2 = V^2/X^2.$$

If the values of the armature current per phase be plotted as ordinates and the corresponding values of the induced E.M.F.'s E as abscissae, the curve so obtained for various loads on the motor at unity power factor will be a hyperbola, of which the apex will lie on the abscissa axis at a distance V from the origin. The same curves will also be obtained if the machine runs as a generator.

Let us now suppose the torque is kept constant and the excitation is varied. The current vector must then move

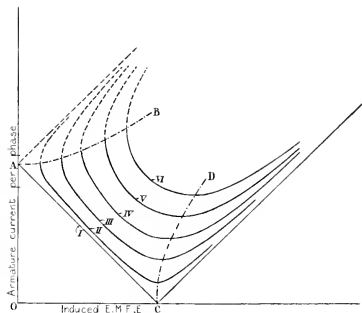

FIG. 3.

along some line such as AJ in Fig. 2. If various points on the line AJ be taken and the corresponding values of the armature currents per phase (i.e. the length of the vector OA) and of the induced E.M.F. E (equal to X times the length of GA) be plotted, a curve such as, say, III in Fig. 3 will be obtained. This is the well-known "V" curve of the synchronous machine, and it refers, as stated above, to a constant load on the motor.

In Fig. 3 a series of such "V" curves have been plotted in this way. The hyperbolas of stability (AB) and unity power factor (CD) are also shown. For the parts of the "V" curves which lie to the right of the hyperbola CD, the armature current leads on the applied pressure, and for those portions of the curves to the left of this hyperbola the armature current lags behind the applied pressure.

PART II.

The influence of the resistance of the armature winding on the circle diagram and on the power of the machine will now be considered, still assuming that the field-system

has non-salient poles. The following E.M.F.'s acting in the armature circuit must now be taken into account:—

1. The E.M.F. due to the rotating field produced by the armature current.
2. The E.M.F. induced by the revolving field-system.
3. The E.M.F. necessary to overcome the armature resistance.
4. The constant applied pressure at the armature terminals.

As before, the action of one phase only will be considered. In Fig. 4, OF represents the constant applied pressure per phase. The vector OB represents the E.M.F.

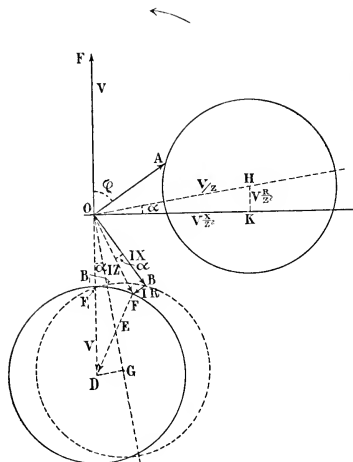

FIG. 4.

induced by the rotating field due to the armature current of I amperes per phase. The armature-current vector OA thus leads on the vector of the resulting rotating field by 90° . The vector BF represents the back E.M.F. corresponding to the armature resistance of R ohms per phase. The vector FD represents the E.M.F. per phase induced by the revolving field-system, and the vector OD is equal and opposite to OF the vector of applied pressure per phase. If the exciting current be maintained constant it follows that the extremity F of the vector DF must move on a circle of radius E , and whose centre is D. Now the shape of the triangle OBF remains constant as the armature current and excitation vary, because the angle OBF is a right angle, and the angle FOB is $\alpha = \tan^{-1} R/X$, and is of constant magnitude. Hence the extremity B of the vector OB must move on a circle whose centre lies on

the line OG inclined at an angle $\alpha = \tan^{-1} R/X$ to the vector OD, and the distance of the centre G from O is $OD \cos \alpha$. Since the current vector OA is always at right angles to and proportional to the E.M.F. vector OB, it follows that the extremity A of the current vector OA moves on a circle whose centre H is on the line OH inclined at an angle α to the abscissa axis. The distance OH bears the same relationship to the distance OG that the length of the current OA bears to the corresponding E.M.F. vector OB, i.e. $OH = OG/X$. But $OG = OD \cos \alpha$, i.e. $OH = V \cos \alpha$. Therefore—

$$OH = \frac{V}{X} \cos \alpha = \frac{V}{X} \cdot \frac{X}{Z},$$

where—

$$Z = \sqrt{R^2 + X^2}.$$

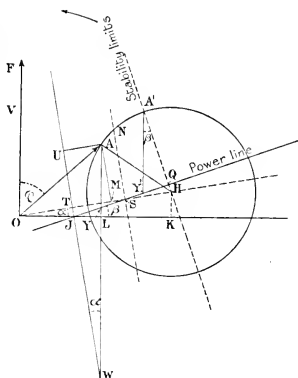

FIG. 5.

The co-ordinates of the centre H of the circle HA are—

$$OK = OH \cos \alpha = \frac{V}{Z} \cdot \frac{X}{Z} = V \cdot \frac{X}{Z^2};$$

$$HK = OH \sin \alpha = \frac{V}{Z} \cdot \frac{R}{Z} = V \cdot \frac{R}{Z^2}.$$

The radius of this circle is—

$$HA = \frac{E \cos \alpha}{X} = \frac{E}{X} \cdot \frac{X}{Z} = \frac{E}{Z}, \text{ because } G B_1 = D F_1 \cos \alpha.$$

It is thus evident that the effect of the resistance of the armature winding is to tilt the current circle so that its centre lies on a line inclined at an angle $\tan^{-1} R/X$ to the abscissa axis.

The power per phase of the machine corresponding to any current vector OA, is the input per phase minus the $I^2 R$ loss per phase, that is to say, it is $V \cdot A \cos \phi - R \cdot O A^2$ (Fig. 5).

Also from Fig. 5—

$$\begin{aligned} O.A'.R &= R[AH^2 - OH^2 + 2.OH.OA'.\cos AOH], \\ &= R[AH^2 - OH^2 + 2.OH.O.M], \\ &= R.O.M.2.OH + R[AH^2 - OH^2], \\ &= R.O.M.2.OH - R.ON^2, \text{ where } ON \text{ is a} \\ &\quad \text{tangent to the circle } HN. \\ &= R.O.M.2.OH - R.OS.OH, \\ &= R.O.M.2.OH - R.2.OT.OH, \text{ where } T \\ &\quad \text{bisects } OS, \\ &= 2.R.OH.MT = 2.R.OH.A.U. \end{aligned}$$

But NS is the polar of the circle HA with respect to O, and TU is the half-polar of the circle HA with respect to O, that is to say, TU is drawn at right angles to OS and passing through T the point of bisection of OS. Hence the perpendicular distance of the extremity A of the current vector from the half-polar of the current circle is proportional to the I'R loss.

Moreover—

$$I^2R = OA'^2.R = 2.R.OH.A.U = 2.R.OH.A.W \sin \alpha,$$

where AW is a line drawn perpendicular to the abscissa axis.

$$\text{The power input per phase} = VI \cos \phi = V.A.L$$

Therefore the useful power per phase

$$\begin{aligned} &= V.A.L - 2.R.OH.A.W \sin \alpha, \\ &= V.A.W - V.L.W - 2.R.OH.A.W \sin \alpha, \\ &= A.W(V - 2.R.OH \sin \alpha) - V.L.W, \\ &= AY(V - 2.R.OH \sin \alpha) + YW(V - 2.R.OH \sin \alpha) - V.L.W, \\ &= AY(V - 2.R.H.K) + YW(V - 2.R.H.K) - V.L.W. \end{aligned}$$

If JY is a line through J inclined at an angle β to the abscissa axis, such that

$$\frac{Y.W}{L.W} = \frac{V}{V - 2.R.H.K'}$$

then the useful power phase will be—

$$AY(V - 2.R.H.K),$$

that is to say, it is proportional to the distance of the extremity A of the current vector from a line passing through the intersection J of the half-polar JU and the abscissa axis, and inclined at an angle β to that axis, where

$$\begin{aligned} \tan \beta &= \frac{Y.L}{J.L} = \frac{Y.L}{L.W \cdot \tan \alpha} = \frac{Y.W}{L.W \cdot \tan \alpha} - \frac{L.W}{L.W \cdot \tan \alpha} \\ &= \frac{Y.W}{L.W \cdot \tan \alpha} - \cot \alpha = \left(\frac{Y.W}{L.W} - 1 \right) \cot \alpha. \end{aligned}$$

$$\therefore \tan \alpha \tan \beta = \left(\frac{Y.W}{L.W} - 1 \right) = \left(\frac{V}{V - 2.R.H.K} - 1 \right)$$

$$\begin{aligned} &= \frac{2.R.H.K}{V - 2.R.H.K} = \frac{2.R \cdot \frac{R}{Z} \cdot V}{V \left(1 - 2.R \cdot \frac{R}{Z} \right)} = \frac{2.R^2}{Z^2 - 2.R^2} = \frac{2.R^2}{X^2 - R^2} \\ &= \frac{2.(R/X)^2}{1 - (R/X)^2} = \frac{2 \tan^2 \alpha}{1 - \tan^2 \alpha'} \end{aligned}$$

$$\therefore \tan \beta = \frac{2 \tan \alpha}{1 - \tan^2 \alpha}, \text{ or } \beta = 2\alpha.$$

Hence the angle JOT = the angle JST, and the power line passes through S, the point of intersection of the polar SN and the line OH.

It is thus seen that the current circle can easily be drawn for any given value of the exciting current and for a given applied pressure, since the co-ordinates of the centre of this circle are $OK = V.X/Z$ and $KH = V.R/Z$, and the radius of the circle is E/Z , where E is the E.M.F. corresponding to the given value of the exciting current. The useful power is given by $(V - 2.R.V.R/Z^2)(AY)$, where AY is the perpendicular distance of the extremity of the current vector A from a line which passes through the intersection of the semi-polar and the abscissa axis and through the intersection of the polar and the line OH on which the centre of the circle lies.

The maximum power for any given value of the exciting current will clearly be given when the extremity A of the current vector lies on the radius HA' which is perpendicular to the loss-line. Hence the maximum power for any given exciting current is—

$$\begin{aligned} W_{\max} &= A'Y'(V - 2.R.H.K) = A'Q \sec \beta (V - 2.R.H.K), \\ &= (A'H - QH) \sec \beta (V - 2.R.H.K) = (AH - SH \sin \alpha) \\ &\quad \sec \beta (V - 2.R.H.K), \\ &= \left(AH - \frac{AH^2}{OH} \sin \alpha \right) \sec \beta (V - 2.R.H.K), \\ &= AH \left(1 - \frac{AH}{OH} \sin \alpha \right) \sec \beta (V - 2.R.H.K), \\ &= \frac{E}{Z} \left(1 - \frac{E/Z}{V/Z} \sin \alpha \right) \sec \beta (V - 2.R.H.K). \end{aligned}$$

For the maximum power which the machine is capable of giving as a motor—

$$\frac{d}{dE}(W_{\max}) = 0, \therefore E = \frac{V}{2 \sin \alpha}.$$

\therefore absolute W_{\max} ,

$$= \frac{V}{2Z \sin \alpha} \left(1 - \frac{1}{2} \right) \left(\frac{1}{\cos^2 \alpha - \sin^2 \alpha} \right) \left(V - 2 \frac{R^2}{Z^2} V \right).$$

But $\sin \alpha = R/Z$, and $\cos \alpha = X/Z$.

$$\begin{aligned} \therefore W_{\max} &= \frac{1}{4} \frac{V}{Z} \cdot \frac{Z^2}{R^2} \cdot \frac{Z^2}{X^2 - R^2} \cdot V \cdot \frac{X^2 - R^2}{Z^2}, \\ &= \frac{1}{4} \frac{V^2}{R^2}. \end{aligned}$$

The point A' on the current circle in Fig. 5 gives the limit of stability, and the limits of stability for various values of the exciting current will be given by the equation—

$$\begin{aligned} OA'^2 &= A'H^2 + OH^2 - 2.OH.A'H \sin \alpha, \\ \therefore I^2 &= \left(\frac{E}{Z} \right)^2 + \left(\frac{V}{Z} \right)^2 - 2 \frac{V.E}{Z^2}, \\ \therefore I^2 Z^2 - E^2 + 2VE.R/Z &= V^2, \\ I^2 Z^2 - (E - V.R/Z)^2 &= V^2 - V^2 R^2/Z^2, \\ I^2 Z^2 - (E - V.R/Z)^2 &= V^2 X^2/Z^2, \\ \frac{1}{(X/Z)^2} - \frac{(V.X/Z)^2}{(V.X/Z)^2} &= 1. \end{aligned}$$

This is the equation of a hyperbola whose vertex is at the point $E = V.R/Z$, $I = V.X/Z$.

Further, the value of $\cos \phi$ will be unity when the extremity A of the current vector lies on the ordinate axis,

and for this condition the following equation will express the connection between E and I :

$$AH^2 = OA^2 + OH^2 - 2 OH \cdot OA \sin \alpha,$$

or—

$$(E/Z)^2 = I^2 + (V/Z)^2 - 2(V/Z) I R/Z,$$

$$E^2 = I^2 Z^2 + 2 V I R = V^2,$$

$$E^2 = (I Z - V R/Z)^2 = V^2 - (V R/Z)^2,$$

$$E^2 = (I Z - V R/Z)^2 = V^2 X^2/Z^2,$$

$$\therefore \frac{E^2}{(V X/Z)^2} = \frac{(I Z - V R/Z)^2}{(V X/Z)^2} = 1.$$

This is the equation of a hyperbola whose vertex is at the point $E = V X/Z$; $I = V R/Z$.

The "V" curves may be deduced from the circle diagram of Fig. 5, but the process is extremely laborious, since the power line JY has a different position for each value of the induced E.M.F., E . By means of the following construction the "V" curves may be deduced with great ease.

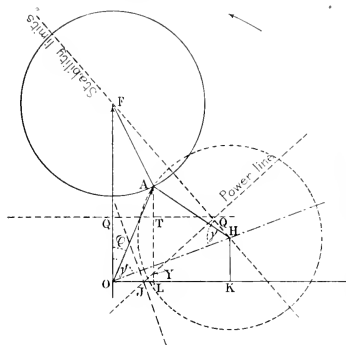

FIG. 6.

The power supplied to the motor per phase is $V I \cos \phi$ watts, where I is the value of the current per phase and $\cos \phi$ is the power factor. If R be the resistance of the armature winding per phase, the power lost in heating the copper is $I^2 R$ watts. Now suppose that the iron and friction losses are constant and represented by W , watts per phase. Then $V I \cos \phi - I^2 R - W = W$, the mechanical power developed per phase. (It will be seen later that in the more accurate vector method of deducing the "V" curves, the variation of the iron loss can easily be taken into account if it be so desired.)

We have then $V I \cos \phi - I^2 R = W - W = W$, and is constant. Therefore $I R = V I \cos \phi - W = V (A L - W/V)$.

In Fig. 6 mark off $TL = W/V$ and through T draw a line parallel to the abscissa axis. Then $FR = V \cdot AT$.

Now it has been shown that OA^2 is equal to $2 OH \times$ distance of A from the semi-polar of the circle HA with respect to the point O . Also $I \cdot R = V \cdot AT$; that is, $OA^2 = (V/R) AT = 2(V/2R) AT$. But $(V/2R) AT$ is constant; hence the point A lies on a circle whose semi-polar

with respect to O is the horizontal line through T . The centre of this circle must lie on the ordinate axis and at a distance from O equal to $V/2R$. Such a circle is shown in Fig. 6 by FA . Since for this circle the condition $FR = V I \cos \phi - W$ is fulfilled, where W is constant, it follows that for all points on circles such as FA the load on the machine is constant. The radius r of the circle FA is given by the geometrical relationship:—

$$r = OF - 2 OQ, OF = (V/2R) - 2(W/V) V/2R,$$

or—

$$r = (V/4R - W/R) : r = \sqrt{\left(\frac{V}{4R} - \frac{W}{R}\right)}.$$

Again, in the circle HA , Fig. 6, we have $OH = V/Z$.

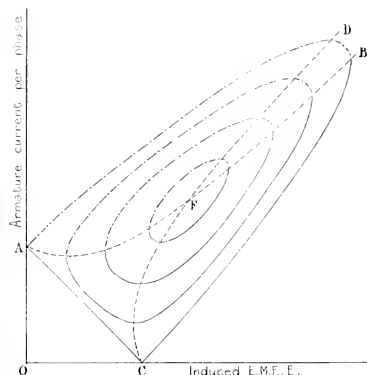

FIG. 7.

In the circle FA we have $OF = V/2R$. The angle $FOH = 90^\circ - \text{angle } HOK$.

$$\therefore OF \cos FOH = \frac{V}{2R} \sin HOK = \frac{V}{2R} \cdot \frac{V}{2R} = \frac{V}{2R}.$$

But $OH = V/Z$.

$\therefore FH = OF$, and the angle $FHO = \text{the angle } FOH$.

The centre of the circle FA is thus immediately obtained by the intersection of the line HF with the ordinate axis, where the angle $FHO = \text{the angle } FOH$. From what has been said it can easily be shown that the line HF gives the stability limits (cf. Fig. 5).

In order to draw the "V" curves for any given mechanical load $W - W_0$, draw a circle with centre F , such that $OF = V/2R$, and of radius $\sqrt{1/4R(V^2/4R - W)}$. Next scale off the current vectors, such as OA , and the corresponding vectors E/X , such as AH , and plot the values of E as abscissae and the corresponding values of I as ordinates.

In Fig. 7 the "V" curves have been deduced from

Fig. 6 in this way for four different values of the load, including no load. It will be noticed that as the load increases, the "V" curves shrink until for a load W , such that $V^2/4 R^2 = W/R$, or $W = V^2/4 R$, the radius of the load circle FA (Fig. 6) becomes zero, and the "V" curve becomes a point (F in Fig. 7). This corresponds to the maximum possible load of the machine as a motor.

The limits of stability are given by the points at which the stability line HF cuts the constant load circles, and if these points be marked on the "V" curves they will be found to lie on the hyperbola AB . The points on the "V" curves corresponding to unity power factor are given by the intersection of the ordinate axis and the constant power circles, and if these points be marked in Fig. 7 they will be found to lie on the hyperbola CD .

PART III.

The results deduced above only refer to the case in which the field-magnet system has a continuous iron surface. When the field-system has salient poles an important modification becomes necessary. Referring to Fig. 8 let the curve represent the M.M.F. wave of the

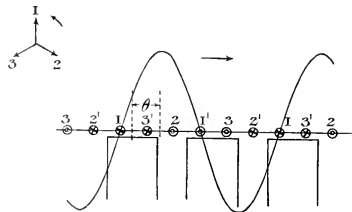

FIG. 8.

revolving field due to the armature current of I amperes per phase, and let F represent the amplitude of this wave. Also suppose that the centre of the pole of the field-system is displaced in space through θ electrical degrees, and that the field-system is unexcited. (The angle θ in Fig. 8 is the

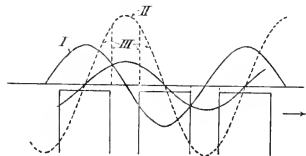

FIG. 9.

same as the angle θ in Fig. 2.) If we resolve the M.M.F. curve into two components at right angles, viz. $F \cos \theta$ in the direction of the pole axis, and $F \sin \theta$ at right angles to the pole axis, the former component represents the direct magnetizing (or demagnetizing) M.M.F. of the armature reaction, and the latter component the cross-magnetizing

M.M.F. of the armature reaction. The flux due to the direct-magnetizing component has a circuit which has constant reluctance for nearly the whole of the M.M.F. curve, and hence the flux curve will have approximately the same shape as the corresponding M.M.F. curve. For the

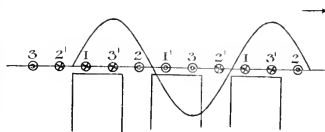

FIG. 10.

case of the cross-magnetizing component of the M.M.F., however, the reluctance of the magnetic circuit has widely different values for different points of the M.M.F. curve, and consequently the flux curve will have quite a different shape from the corresponding M.M.F. curve. In Fig. 8

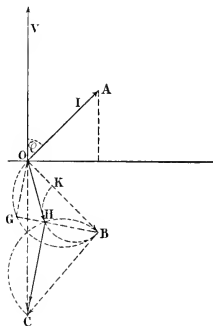

FIG. 11.

the curve shows the rotating M.M.F. wave due to the armature current when the field-system has a continuous iron surface. The curve passes through its zero value when it cuts the conductor in which the current has its maximum value. It is thus clear that there can be no torque exerted between the field produced by this resultant M.M.F. and the conductors of the armature, for they are displaced by 90° relatively to each other. In Fig. 9 curve I represents the direct-magnetizing component ($F \cos \theta$) of the M.M.F. curve of Fig. 8, and curve II will also represent the flux due to this direct component of the M.M.F., since the reluctance of the magnetic circuit for this component is approximately constant at all points. In Fig. 9 curve III represents the cross component of the wave of Fig. 8; thus curve II of Fig. 9 has a maximum value $F \sin \theta$,

where F is the maximum value of the curve of Fig. 8. Curve III of Fig. 9 shows the flux due to the M.M.F. curve II. If curve III be analysed its first harmonic will be found to have an amplitude $F \sin \theta [b/\tau - 1/\pi \sin(b/\tau)\pi]$, where b/τ is the ratio (pole breadth)/(pole pitch).² The first harmonic is shown as a full line curve in Fig. 9.

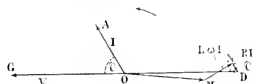

FIG. 12.

The two components $F \cos \theta$ and $F \sin \theta [b/\tau - 1/\pi \sin(b/\tau)\pi]$ shown in Fig. 9 may now be combined to give the actual magnetic field due to the armature currents, and if this be done the curve shown in Fig. 10 will be obtained. It should be noticed that this curve is now displaced relatively to the curve of Fig. 8, and consequently there is a torque produced between the armature conductors and

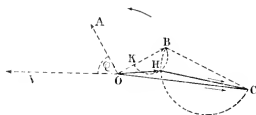

FIG. 13.

the field due to the armature current. Hence when the machine has salient poles there is a torque developed even when the field-system is unexcited, the armature current itself supplying a magnetizing component. It may even happen that a driving torque will be produced when the exciting current is reversed in direction.

In order to obtain the connection between the E.M.F., E , induced by the field-system and I , the armature current per phase, the following construction may be used:—

In Fig. 11 let the vector OA represent the armature current, I per phase, and OB the E.M.F. which would be

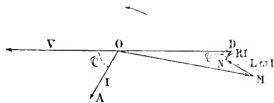

FIG. 14.

induced by the armature current I if the ratio b/τ were unity, that is, if the field-system had a continuous iron surface. If CH represent the induced E.M.F., E , we may resolve OB into a component OG parallel to CH , this component will represent the direct-magnetizing or demagnetizing effect, and is, within limits, unaffected by the salient poles. The component GB of OB which is at right angles to the component OG is reduced by the salient poles in the ratio $[b/\tau - 1/\pi \sin(b/\tau)\pi]$, where b/τ is the ratio of the pole width to the pole pitch, and thus OH will be the induced armature E.M.F. actually due to the

rotating armature field. Now G lies on a circle drawn on OB as diameter, and since the ratio GH/GB is constant, H must lie on a circle whose diameter is—

$$KB = \frac{HB}{GB} \cdot OB.$$

Further, H must lie on a circle whose diameter is CB , because the angle CHB is a right angle. Hence H is

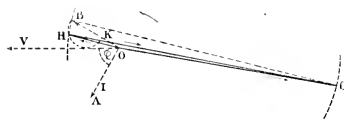

FIG. 15.

the point of intersection of circles on the diameters KB and CB respectively.

In analysing armature reaction by the Blondel or any other similar method, let i_a represent the exciting current

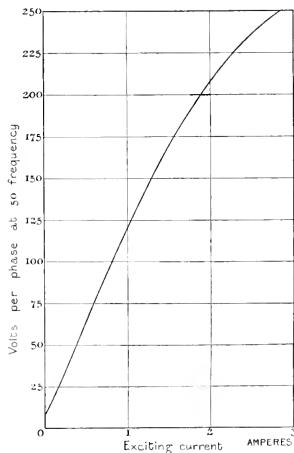

FIG. 16.

which is equivalent in its magnetic effect to a pure demagnetizing current of i_a ampere per phase. Further, let—

$L\omega$ be the leakage reactance per phase of the armature winding, so that $L\omega I$ will be the induced volts per phase due to the leakage flux for a current of I amperes per phase;

and let R be the effective resistance per phase of the armature winding under the working conditions.

* See E. ARNOLD, "Die Wechselstromtechnik," vol. 4.

Referring to Fig. 12, let $O A$ represent the current of 1 ampere per phase and $O G$ the applied voltage V per phase. Then $O D = O G$ will represent the induced back E.M.F. per phase. Draw $D N$ parallel to $O A$ and equal in magnitude to $R I$. Also draw $N M$ perpendicular to $D N$ and

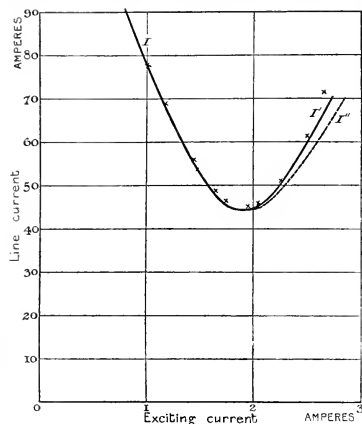

FIG. 17.

Curve I'' .—Calculated values assuming the value of the leakage reactance $L \omega$ to be constant and equal to 0.07 ohm.

Curve I' .—Calculated values, the value of $L \omega$ for lagging currents being taken the same as for Curve I'' , i.e. 0.07 ohm. The value of $L \omega$ for leading currents is taken as 0.78 ohm.

The points marked x give the experimentally determined values.

make $N M$ equal in magnitude to $L \omega I$ the induced volts due to the leakage flux per phase. Then $O M$ will give the magnitude and phase of the volts per phase induced by the rotating field due to the combination of the field due to the exciting current and the rotating field due to the armature current. In Fig. 13, $O C$ is drawn in the same direction as $O M$ in Fig. 12, and the magnitude of $O C$ represents the exciting current necessary to induce the voltage $O M$ per phase (Fig. 12). The exciting current $O C$ is read off from the open-circuit characteristic of the machine.

Draw $O B$ at right angles to $O A$ and lagging 90° behind $O A$. It follows from what has been said previously that $O B$ represents the direction of the rotating field due to the armature current.

The exciting current corresponding to an armature current of 1 ampere per phase is I_e . In Fig. 13 draw $O B$ to represent I_e amperes to the same scale as $O C$ is drawn. The geometrical construction shown in Fig. 11 is now made and corresponding points in Figs. 11 and 13 are, for the sake of clearness, marked with the same letters.

From $O B$ mark off $O K$ equal to $F \sin \theta [b/\tau - 1/\pi \sin (b/\tau)\pi]$, where b/τ is the ratio of the pole width to the pole pitch. On $B K$ and $B C$ draw circles. If these two circles intersect at H , then $H C$ represents the exciting current

necessary when the armature current is 1 ampere per phase and the angle of lag is θ . By means of this construction the "V" curves may be calculated. For, knowing the load on the machine, assume any value of the armature current, I amperes per phase. Calculate the corresponding value of θ and determine by means of the above construction the corresponding value of the exciting current. In Figs. 14 and 15 the vector diagrams are shown for the case in which the current is leading.

PART IV. COMPARISON OF THE RESULTS DEDUCED FROM THE THEORY AND THOSE EXPERIMENTALLY OBTAINED.

Tests were made on a three-phase 20-kw. mesh-connected synchronous motor. By means of the Blondel test it was found that the leakage reactance $L \omega$ was 0.07 ohm per phase for a frequency of 50. The Blondel test also showed that 0.015 ampere in the exciting circuit was equivalent to 1 ampere per phase in the armature winding. The resistance per phase of the armature winding was taken as 0.15 ohm. It is difficult to measure the effective value of the resistance of the armature winding under running con-

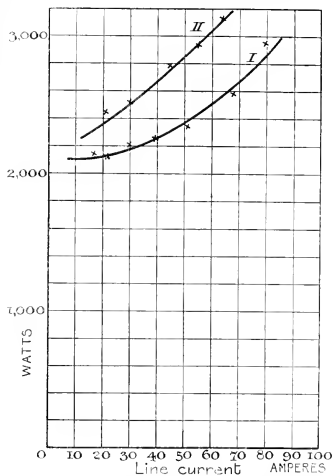

FIG. 18.

Curve I shows the power necessary to drive the synchronous motor when running light and under-excited.

Curve II shows the power necessary to drive the synchronous motor when running light and over-excited.

ditions, but from the results of some experiments the above value was considered to be approximately correct.

From the dimensions of the machine the value of $[b/\tau - 1/\pi \sin (b/\tau)\pi]$ was found to be 0.345 .

The open-circuit characteristic of the machine is given in Fig. 16. The tests were made with a constant supply pressure of 200 volts between the armature terminals,

Making use of the construction shown in Figs. 12, 13, 14, and 15, and using the numerical values given, the "V" curve shown in Fig. 17 by the curve "1" was deduced. The experimentally obtained points are indicated by crosses in the same diagram (Fig. 17). It will be noticed that for lagging currents (*i.e.* for small values of the excitation) the agreement between the calculated values and the experimentally obtained values is sufficiently close, but for leading currents (*i.e.* for large values of the excitation) there is a considerable divergence. It was not easy to see how this divergence could be explained, for although one naturally suspected the saturation of the magnetic circuit to have something to do with it, the construction of Figs. 12-15 has already allowed for the varying saturation of the main magnetic circuit.

A test was made with the synchronous motor running light, and the input was measured for various values of the armature currents, from a large lagging to a large leading current. The points obtained in this test are shown in Fig. 18. The fact that the input is much larger for a given value of the current when leading than for the same value of the current when lagging, showed that the iron losses were greater in the former case than in the latter, and consequently the flux density must therefore have been greater for a leading current than for a lagging current, as might have been expected from an inspection of Figs. 12-15.

This suggested that the value of the leakage reactance would also vary according to whether the current were lagging or leading. For leading currents the increased

flux density in the armature teeth would cause the leakage reactance L_{ω} to have a smaller value than that deduced from the Blondel test, in which low flux densities are dealt with. This assumption seemed to be confirmed by sending a high-frequency current through the armature winding when the machine was standing, and measuring the ratio (volts)/(amperes per phase) for different values of the exciting current.

From an examination of the results of this test the mean value of L_{ω} was taken to be 0.78 ohm for leading currents, while the value 0.07 ohm was retained for lagging currents. By recalculating the branch of the "V" curve corresponding to leading values of the current, and using the value 0.78 ohm for this branch, the "V" curve "1" was obtained. It is to be noticed that the calculated values and the observed values now agree well throughout the whole range. It may be remarked here that if the value of the exciting current was increased beyond the largest value given for the tests in Fig. 17, *viz.* 2.65 amperes, the machine became unstable and easily fell out of step. This may be accounted for by the continued diminution of the value of the leakage reactance L_{ω} , due to saturation. This further diminution of the value of L_{ω} is also sufficient to account for the divergence from the calculated curve "1" of the experimental point for an exciting current of 2.65 amperes.

The tests that have been made in connection with this paper have been many and laborious, and I wish to make acknowledgment of the service rendered by Mr. W. T. Davis in assisting with these tests.

ADDRESS TO THE STUDENTS' SECTION.

THE FOOD SUPPLY AND THE ELECTRICAL ENGINEER.

By C. V. DRYSDALE, D.Sc., Member.

(Address delivered 26th November, 1913.)

In giving for the second time the opening address to the Students' Section, I should like first to express my appreciation of the invitation to do so. On the previous occasion I found it necessary to deal with some matters of a somewhat controversial character, which gave rise to adverse comment in certain sections of the technical press, although my views were equally strongly supported by others. My reasons for taking this course were that, as an instructor of young electrical engineers, I felt it a matter of duty to them to look facts fairly in the face as regards their future prospects; and the reports which have reached me from time to time since have not led me to modify the opinions then expressed. On the contrary, I still feel most strongly that if young electrical engineers are to attain a success in life in any way commensurate with the training and intelligence required to qualify themselves, there must be either some great change in the industry, or they must launch out as far as possible in new directions. This evening I propose to deal specially with a recent development which is of the

greatest importance to the community as a whole, and which therefore ought to offer good opportunities to the coming generation of engineers.

It is curious to observe how little the human race concerns itself with the most fundamentally important matters in connection with its own welfare. Upon what does the prosperity of a community and of its industries in general depend? Most people look at it simply from the monetary standpoint, and are quite satisfied if they manage to produce something which they can get the public to buy, whether it is of any real value or not. This policy is all right from the standpoint of the immediate self-interest of the individual, but it may be a very mistaken one from the point of view of the community, and of the individual himself in the long run. I have not a word to say against the natural desire of any student to "get on" as well as he possibly can. Quite the contrary. But although certain individuals may temporarily succeed by being "smart" business men in the modern sense of the term, I very much

doubt whether their success will endure, and it is highly probable that in the end they will seriously lose by it. The road to success (however many apparent instances there may be to the contrary) is through the ability to produce something which is really necessary for the public welfare, combined with the ability to convince the public that one has done so.

Now what is it that the human race needs most of all? The answer is simple; it needs food. Very few people realize that the prosperity of the community as a whole and of every industry is really as dependent upon agriculture as it was before the industrial era set in. There is an impression, which is fostered by writings such as those of Prince Kropotkin, that the world is capable of easily satisfying the needs of everybody; and consequently few even of the professed economists have any working explanation of the origin of industrial depression and unrest. And yet, if this idea did not blind us to the facts, we should most of us see that the food question is at the root of the whole industrial problem. Most of my audience know that this country at the present time produces only about half of the food it consumes, whether it is capable of producing it all or not. Now, where and how do we get the remainder? We get it from other countries whose industries are in a less developed state, such as Russia, Canada, and Australasia, and who send us food in exchange for our manufactures, which they need for two principal purposes—the satisfaction of their other needs, such as clothing and luxuries, and the improvement of their agriculture and means of transport, such as is provided by agricultural implements, railways, steamships, etc. So long as these other countries have an excess of food, and have not developed, or cannot develop, on the industrial side, this arrangement is of mutual advantage.

But what does this mean from the industrial standpoint? In order to produce anything, the workers have to be fed, and the wages paid to the ordinary workpeople are almost equivalent to doles of food given them while the work is being done. About 2,500,000 adult men workers in this country earn wages of 25s. a week or less, and the greater proportion of their wages has to be spent on food for themselves and their families. If we could only get out of the habit of thinking in terms of money (however useful money may be as a means of exchange) and of the idea that the total food supply is ample, we should see in an instant that the prosperity of an industry and of its workers depends almost entirely upon the total food supply and upon the share of it which the community as a whole will give to the industry as a recognition of the value of its products or services.

It follows that if the total food supply is inadequate, not only humanitarian considerations but self-interest should lead people as far as possible to undertake work which directly or indirectly leads to an increase of food and of the proportion of the total supply produced or brought into this country.

Now, is the food production of the world sufficient to feed its inhabitants? The majority of people will say yes, but they are not as a rule those who have had any experience of agriculture or who have studied the subject very fully. Prince Kropotkin is an exception; but his interesting works, which appear so convincing, are marred by a complete failure to appreciate the crux of the question, *i.e.*

that the total production of food is limited by the amount of available fertilizing material, and his conclusions lose all their value in consequence.

It has long been realized by those who have studied economic or biological questions that human life, like that of the lower animals, continually presses against subsistence, and that large numbers of people in this and other countries perish annually from starvation or the diseases which under-nutrition render them unable to fight against. This conclusion, which is obvious on rational biological principles, has been hotly contested, but the vital statistics of recent times strongly confirm it by showing a very close connection between the birth and death rates of different countries and of the same country at different times; and M. G. Hardy, a French statistician, has carefully compared the production of food in the civilized world with the needs of its inhabitants, and as a result finds that if the whole of the food produced were fairly distributed among men, women, and children, each would get a ration of proteids of only two-thirds of that required for full health and strength.

Sir William Crookes, now President of the Royal Society, devoted his Presidential Address to the British Association in 1898 to the wheat supply, and came to the conclusion that the world's available supply of nitrates would lead to an exhaustion by the year 1931 at the then rate of progress, a conclusion which has been endorsed this year by Professor Dixon in his Presidential Address to the Geographical Section of the Association. Sir William Crookes actually definitely predicted the rise of food prices which has been so marked lately, and that the United States, which was then a large exporter of corn, would soon cease to be so, a prophecy which has been decidedly fulfilled, as is shown by the latest publications of the Board of Agriculture.

There can be no reasonable doubt to any unprejudiced observer that there is a serious deficiency in the amount of food at present produced, and that this deficiency is likely to be more serious as time goes on. This is at the bottom of most of the difficulties of our time, of low wages, of unemployment, overcrowding, etc., and if these difficulties are to be overcome in the future, either some means must be found for increasing the production of food, or the production of human life must be considerably checked. So little do I believe that the production of food can be (or at least will be) greatly accelerated that I have felt it my duty since I had an opportunity of chance to devote my energies to the latter problem, but I shall be delighted to be proved in error, and I want to show you how you can best set about proving me wrong. If I am right, you will be both helping to increase the food supply and be making great profits, owing to your inability to keep pace with the demand. If I am wrong, and you are easily able to increase the food supply, you will do enormous service to the community by ridding it of most of the great social evils, and you will yourselves inevitably participate in the universal prosperity.

For the growth of vegetation several things are necessary, but we need only deal at present with those of which there appears to be a general or local deficiency. These are six in number: nitric acid, phosphoric acid, potash, lime, moisture, and sunshine. In many cases, as for instance in parts of India and South Africa, the rainfall is so small that it is not more than half of that necessary to produce a full crop, although the other fertilizing ingredients are probably present in ample quantity. Great

advances have been made in such regions by irrigation, and recently by what is called "dry farming," in which special methods of retaining the water in the subsoils are employed. These processes are only of interest to electrical engineers in so far as machinery is used which can be electrically operated, but electrical ploughing is coming more and more into use, and if it were adapted to the deep subsoil ploughs and other devices employed in dry farming, it might have a considerable field in places like South Africa, where power is sometimes available. A more speculative, but possibly important, electrical application might be the electrical production of rain. It is well known that in countries where the air is very pure precipitation often does not occur owing to the absence of sufficient "condensation nuclei." The erection of masts with pointed conductors charged to a high negative potential might provide sufficient free electrons (which act as condensation nuclei) to produce the required rainfall.

Turning to the question of the chemical constituents, such as nitric and phosphoric acids and potash, we are confronted immediately with a paradox which has very greatly obscured the subject. There appears to be very little doubt from recent analysis that the ordinary soil contains both nitrogen, phosphorus, and potash sufficient to supply all the requirements of ordinary crops for many years to come. An analysis of the soil in the Broadbalk field at Rothamsted (the well-known experimental farm in Hertfordshire) showed that in the top 9 inches of the soil, weighing 2,500,000 lb. per acre, there were 2,500 lb. of nitrogen, 6,750 lb. of potash, and 2,750 lb. of phosphoric acid, although the field had not been manured for 50 years. Similar or greater amounts have been found in American soils. As an ordinary crop of wheat of 30 bushels to the acre only removes 48 lb. of nitrogen, 21 lb. of phosphoric acid, and 35 lb. of potash from an acre, and the richest crop, cabbage, takes 213 lb. of nitrogen, 125 lb. of phosphoric acid, and 514 lb. of potash from an acre, it will be seen that there should be ample nourishment in unmanured soil to provide for heavy crops for 20 or 30 years.

Unfortunately these analyses appear to be totally misleading, in that the bulk of these materials are not in a state which can be dissolved by plant juices. They are of value, however, in that they indicate the possibility of processes (perhaps electrochemical ones) by which these fertilizing materials may be rendered available. So far as is at present known, they become available at a slow and nearly constant rate by the "weathering" action of sun and air, combined with the action of certain bacteria in the soil. For these bacteria to do their work, however, it is essential that the soil should be basic in its character, hence the desirability of the presence of lime. The amount of available nitric acid in the soil is increased by the rain, which brings down from 3 to 5 lb. of nitrogen to the acre at Rothamsted. It is possible also that the increased yield of crops found in Sir Oliver Lodge's electrification experiments may have been due to the production of nitric acid by the discharge from the wires stretched across the field. On the other hand the rain washes the available nitrogen out of the soil to a considerable extent, the loss having been as much as 37 lb. per acre from an unmanured fallow at Rothamsted.

It is the nitric acid which is as a rule the most deficient

ingredient in ordinary soil, and it was upon the amount of available nitrates that Sir William Crookes based his remarkable prediction as to the rapid approach of the limit of the wheat supply. He did not, however, content himself with this prediction, but indicated how he thought that the serious difficulty could be solved. In 1892 Sir William Crookes had himself shown an electric wire by which the union of the nitrogen and oxygen of the air was made to take place. It is interesting to note from an address given by Mr. L. de La Vallée Poussin to the Académie de Rouen last year that the same question agitated the minds of notable Frenchmen 150 years ago. Mr. Dufourmy appears to have addressed a strong manifesto to the Academy in those days, pointing out that the happiness of the human race depended on saltpetre, and asking all patriotic citizens to do their best to conserve it. At the time of the French Revolution such a declaration was signed by the members of the famous Committee of Public Safety, and five years afterwards Mr. Chapta! pointed out that the best process of producing a greater quantity of nitrates was the union of the nitrogen and oxygen of the air by means of the electric spark.

All these speculations concerning the food supply were pushed on one side, however, first by the Napoleonic Wars, and second by the great influx of food from the New World: and it is only within the last few years that the warning has again come to us that the food-producing capacity of the whole world is insufficient for its population, and that there is urgent need for fertilizing material.

THE DIRECT OXIDATION OF NITROGEN.

In 1905 the Norwegian engineer, Mr. S. Eyde, commenced to apply the special form of arc devised by Professor Birkland to the commercial production of nitric acid. The latter had discovered that the essential needs for the efficient oxidation of nitrogen were a heating in the arc to 3,500° C., combined with a very rapid after-cooling to below 800° C. to prevent redissociation. To get as large a heating surface as possible he employed a high-potential alternating-current arc between long water-cooled electrodes across which a strong unidirectional magnetic field was maintained. At each reversal of the current an arc was formed, which was blown outwards by the magnetic field and travelled along the electrodes in the form of an expanding semicircle. With one direction of the current the arc was blown out on one side, and with the reverse current it was blown out on the other side. The result of the successive reversals of current, therefore, was to produce a perfect disc of concentric arcs travelling outwards like ripples on a pond, and in the latest furnaces of 400-kw. capacity each, these discs are 10 ft. in diameter.

The furnace consists of a thick hollow disc of refractory material into which the poles of a powerful electromagnet penetrate axially. The two hollow water-cooled electrodes penetrate the central chamber from the two ends of a diameter, and are supplied with alternating current at a pressure of 5,000 volts. In order to strengthen and support the furnace and to supply the air to be converted into nitric oxide a hollow iron drum surrounds the refractory disc to which air is supplied under pressure. The walls of the furnace are perforated, so that the air pene-

trates perpendicularly to the disc of flame, after which it escapes by the periphery into a pipe which conveys it to the cooling, oxidizing, and absorption towers. It first passes through a tubular boiler, thus raising steam for purposes to be described, then through a refrigerator, to the oxidation towers, which consist of long vertical iron cylinders in which the nitric oxide takes up more oxygen to form the brown nitric peroxide. Thence it passes to the nitric acid towers, which consist of granite and are filled with broken quartz over which water trickles, the nitrogen being further oxidized and dissolved to form nitric acid. The reactions are as follows:—

The nitric oxide again developed in the last process might be returned to the oxidation towers, but as it is very dilute it is found more convenient to pass it into alkali towers containing chalk or soda, which rapidly absorb the bulk of the gas to form nitrates. There is also a "hot dry absorption process" devised by Mr. Schlesing, in which the gases issuing from the furnace and sufficiently cooled are passed direct into chambers filled with quicklime, which rapidly absorbs the oxides and forms nitrate of calcium. This is much more simple and direct than the wet process, which on the other hand has the advantage of giving a greater variety of products. From the point of view of agriculture, however, the nitrate of lime, as it is called, is very suitable, as it contains two of the constituents which are necessary to the soil.

The success of the Birkland-Eyde process has led to other attempts at attaining the same results, and those of Mr. Schönherr of Basle and of Mr. H. Pauline of Gelsenkirchen appear to have been commercially successful. The latter resembles the Birkland-Eyde furnace, except that the movement of the arc is attained by the well-known horn-break, instead of the magnetic blow-out. These horns, supported by water-cooled electrodes, are enclosed in a vertical furnace supplied from below with preheated air travelling with a velocity stated as about 1,200 ft. a second. It leaves the furnace at a temperature of about 1,000° C., and passes through the usual cooling, oxidizing, and absorption towers. With alternating current at 6,000 volts 50 \sim a series of arcs are formed making a triangular sheet of flame, and a separate blast of cold air is directed at the tip of this flame to assist in the rapid cooling of the oxidized air.

In the Schönherr furnace, which is also employed in Norway, the arc is formed by a 4,000-volt 50 \sim supply in an iron tube 16 ft. long, through which a whirling current of air passes. The air is preheated to about 500° C. by passing through jackets round the central tube, which it afterwards enters at the bottom and ascends rapidly with a whirling motion, thus keeping the arc central. A water-cooled electrode is introduced into the tube at the bottom, and the other electrode is formed by the iron tube itself. The air, however, carries the arc to the full length of the tube, at the upper end of which there is a cold-water jacket that produces the requisite sudden cooling of the gases. The rapid development of this work is shown by the fact that in 1903 two experimental plants of 25 h.p. and

160 h.p. were started, while last year there were the following in the region of Notodden:—

Svaeflos	...	40,000 h.p. in operation
Lienfos	...	15,000 " "
Rjukan	...	120,000 " "
Vamma	...	74,000 " "
Tyin	...	80,000 " "
Total	...	289,000 h.p. in operation

It is stated that 500,000 h.p. will probably be utilized for this purpose by the year 1916.

As regards the equipment, the principal station at Rjukan is fed from the river Maana, which has a regulated flow of 47 cubic metres per second. Ten conduits of 155-cm. diameter carry the water to the ten Pelton-type turbines, each of 15,700 h.p. running at 250 revs. per min. The generators are of 17,000-k.v.a. capacity, each with a power factor of 0.6 (this low power factor being due to the arcs and their necessary series inductance). Power is developed at a pressure of 10,000 volts three-phase at a frequency of 50 \sim per second, and is transmitted about three miles by ten sets of overhead conductors partly of copper and partly of aluminium.

Apparently there is little to choose between the different types of furnace as to efficiency, and with the Birkland-Eyde process one kilowatt-year gives 500 to 550 kilograms of nitric acid, or 853 to 938 kilograms of nitrate of lime containing about 13 per cent of nitrogen. This implies a yield of 111 to 122 kilograms combined nitrogen per kilowatt-year, and as each quarter of wheat requires about 5 kilograms of fixed nitrogen, this is equivalent to about 24 quarters of wheat per kilowatt-year.

THE CALCIUM CYANAMIDE PROCESS.

We may now turn to a quite different process for the production of nitrogenous fertilizers, which is now in extensive operation, although it is less direct than the Birkland-Eyde process. In 1897 Drs. Franck and Caro discovered that barium and calcium carbide, when heated, absorbed nitrogen to form the corresponding cyanamide, the reaction in the case of calcium carbide being as follows:—

They further found that when this calcium cyanamide was treated with hot water it decomposed, giving off ammonia—

Both of these materials are of considerable value to the soil, and it is further claimed that the granular carbon formed in the first reaction is of great service in absorbing and destroying injurious waste products from plants. It has the advantage over nitrate of lime in being less deliquescent and possessing a higher percentage of nitrogen, but it is somewhat slower in action, as the ammonia has to be oxidized to nitric acid in the soil.

In 1906 the Alby United Carbide Factories were formed at Alby in Sweden with an extension to Odda in Norway, where a great amount of water power is available. They then erected a Linde plant for the manufacture of nitrogen, and started the process of cyanamide manufacture by an

* 107,000 h.p. additional to be employed.

associated company, the North-Western Cyanamide Company. The scheme rapidly developed, and a large number of these interests have been combined into the recently formed company, Nitrogen Products and Fertilizers, Limited, which, besides controlling this process and plants, has rights to several great sources of water power. At Odda 83,000 h.p. are already in use, and 125,000 h.p. will soon be available. There are now 20 carbide furnaces taking 1,400 kw. each, and ten 3,500 kw. each. They are almost continuously charged with powdered anthracite and burnt lime, and the molten carbide is tapped off every 45 minutes. It is then cooled, crushed, and ground to fine powder, in readiness for the conversion to cyanamide.

This process is a very simple one, the carbide being fed into vertical cylindrical furnaces or ovens having a cardboard tube down the centre and cardboard partitions at intervals, which are burnt up when the furnace is in operation, thus allowing the nitrogen gas to circulate freely among the carbide. Down the centre of the furnace is a carbon rod which is raised to incandescence by an alternating current, thus bringing the temperature of the furnace up to 800-1,000° C., at which it is kept for about 25 hours. After 35 hours the absorption of nitrogen as shown by a pressure gauge is complete, and the cyanamide is extracted in the form of black fragments, which are crushed and rolled until it forms a fine grey powder. As there is a small proportion of unconverted calcium carbide left, which would be liable to cause fire, it is treated with atomized water to dispel all acetylene, and the final product, known as nitrolim, is treated with a small proportion of petroleum to prevent further absorption of moisture. Its composition as sold is approximately as follows:—

Nitrogen, 18 %, equivalent to ammonia	21.85 %
Free lime	20 % to 30 %
Lime in combination	20 % " 30 %
Carbon	10 % " 12 %
Oxides of iron and alumina	2.5 %
Siliceous and other inert mineral substances	8 % " 10 %

The simplicity of this process and the convenience of the product have led to its very rapid utilization. At Odda 83,000 h.p. is already used, and 125,000 h.p. will shortly be employed. The larger generators are of 12,500 kw. at 120 revs. per min., and the new ones will be of 15,000 kw. The current is generated at 12,000 volts three-phase, reduced at the carbide furnaces to 50 volts, and at the cyanamide furnaces to 60-75 volts. The nitrogen for the latter is produced by the largest Linde air liquefaction plant in the world, 100 tons of air being liquefied daily, giving off 77 tons of nitrogen (the nitrogen boiling at a lower temperature than the oxygen). The present output of the Odda factory is 80,000 tons of cyanamide annually, which is used principally as a fertilizer, but also as a basis for the manufacture of many nitrogen compounds, including explosives. The cheapest chemically-pure ammonia is produced by treating the cyanamide with superheated steam, and it is converted into nitric acid by the Oswald catalytic process.

This process has already been adopted in a number of countries, notably Italy, Switzerland, France, Germany,

Japan, and the United States, the total production in 1912 being about 200,000 tons of cyanamide. Very large extensions are, however, proposed. It is interesting to note that one of the German factories obtains its power from gas engines. A plant will shortly be erected in this country to provide a certain source of nitrates for the manufacture of explosives in case of war.

In conclusion we may consider for a moment what the present and future needs of the community are as regards fertilizing material, and what has been done or is likely to be done as regards satisfying them. Up to the present it appears that the annual production of fixed nitrogen has reached 35 million lb. by the Birkland-Eyde and allied processes, and 90 million lb. by the Franck-Caro process, making 125 million lb. in all. As a quarter of wheat requires about 10 lb. of nitrogen, this output should have increased the world's output of corn by 12½ million quarters.

The world's harvest of 1911 has been given as follows:—

Wheat	457 million quarters
Barley	174 " "
Oats	476 " "
Maize	466 " "
Total	1,573 million quarters

Hence, even if we assume that the whole of these nitrogen products had been used in agriculture, they would have been barely equivalent to 2½ per cent of the wheat harvest, or 1 per cent of the total harvest of cereals. It would need a supply about 50 times as great, or more, to supply even the present needs of humanity.

From physiological data it appears that the average adult man requires 20 grammes of nitrogen daily, or 73 kilograms annually. With the present world population of 1,700 millions, and allowing for age and sex distribution, this means an annual requirement of approximately 10,000 million kilograms. If we were to assume that the population was properly fed at the present time, and that we had only to provide for its increase, we find that in countries where little restraint on fertility takes place the birth-rate is 50 per 1,000, while where there is little poverty the death-rate is only 10 per 1,000. If therefore we are to provide for the natural increase of humanity, we must allow for a 40 per 1,000 or 4 per cent compound interest increase of population. This means a doubling each 17½ years, or a 50-fold increase in a century.

From this it appears that if all the fixed nitrogen produced were conserved and sold in the best possible manner for food, 400 million kilograms additional would be required each year, increasing at compound interest to 800 million kilograms in 18 years, and to 40,000 million kilograms in a century. At the present yield of 120 kilograms per kilowatt-year this would require a plant of 6½ million kilowatts, running continuously, increasing to 330 million kilowatts at the end of a century.

Of course we are not yet entirely dependent upon electrically produced fertilizers. The output of the Chili nitrate beds has increased from 1½ million tons in 1908 to 2½ million tons in 1912, but at this rate it appears probable that they will be exhausted within the next 20 years. Sulphate of ammonia, derived from gas manufacture, etc., is another important fertilizer, but relatively small in amount,

and everybody knows that the time has come for the economizing of coal.

There is no theoretical impossibility of producing all that is required. The fixation of nitrogen is a high-potential endothermic reaction, involving about 3,000 grammes-calories per gramme of fixed nitrogen. I have calculated that if the solar energy could be collected and utilized, the energy falling on 17 square kilometres, or less than a square mile, of the earth's surface would suffice for the 400 million kilograms required for the increase of the world's population, apart from the present deficit. The concentration of the sun's radiation to a focus by a large system of mirrors might possibly cause direct union of the nitrogen and oxygen of the air at its focus; but radiation calculations render this unlikely, as the theoretical limit of temperature by the Stefan-Boltzmann law works out at $3,500^{\circ}\text{C.}$, and the actual attainable temperature would necessarily be considerably lower. There is the possibility also that suitable electrolysis of the soil might do something to liberate the large stores of fertilizing material which at present exists in an insoluble form.

On the other hand, there is the possibility of making the present available nitrogen do double duty by doubling the frequency of crops. Apart from heating the air or soil, there is the supply of artificial sunshine, or ultra-violet radiation from quartz mercury-vapour lamps, which are already coming into considerable use in cultivation under glass.

All these things show that the opportunity for the electrical engineer to affect beneficially the existence of the community is very great, both as regards producing the plant for the great developments that will undoubtedly take place in these processes, and in devising new methods

of fertilizing and stimulating plant growth. Sir William Crookes indeed stated, in the Presidential Address referred to, that the electrical or chemical production of fertilizers would put an end to all anxiety respecting the food supply. In this I cannot follow him.

It is 15 years since his address, 21 years since his announcement of the possibility of fixing nitrogen electrically, and over 120 years since the declaration of the *Comité de Salut Public*, and we have a deficit of at least 30 per cent in the world's food supply, and the production of fixed nitrogen has not yet affected it by 1 per cent. Observation of vital statistics leads me to the conclusion that 150,000 to 200,000 people die every year in this country as the result of under-nutrition, $2\frac{1}{2}$ millions or more in Russia, 8 millions in India, and an even greater number in China. The deficit of food is not only a menace for the future, it exists and always has existed, owing to the inability of agriculture to keep pace with the growth of numbers; and in my belief the control of the output of human life is necessary, and will always be necessary, if starvation is to be avoided. But, as I said at the outset, I may be wrong, and the best way to prove it is to get these new processes into operation as quickly as possible. In the hope that some of you will be able to take your share in this great humanitarian work, and reap the benefit that will certainly accrue from it, I conclude by wishing every success to the Students' Section.

For the technical information in this address I am indebted to the Norsk Hydro-Elektrisk Kvalstofaktieselskab and the Nitrogen Fertilizers Company. I am also much indebted to the paper read before the Royal Society of Arts on 15th May, 1912, by Mr. E. K. Scott, and reproduced in *Nature* of 4th and 11th July, 1912.

INSTITUTION ANNOUNCEMENTS.

THE FARADAY SOCIETY.

The Council of the Institution has been asked to bring to the notice of the members the arrangement by which members (except Students) of certain cognate societies, of which the Institution is one, may be admitted to membership of the Faraday Society without payment of the usual entrance fee of One Pound, and without the customary signatures. Full particulars can be obtained on application to the Secretary of the Faraday Society, 82 Victoria-street, London, S.W.

INTERNATIONAL ELECTRICAL CONGRESS, SAN FRANCISCO, 1915.

An International Electrical Congress will be held at San Francisco from the 13th to the 18th September, 1915, during the Panama-Pacific International Exposition. The Congress, which has been authorized by the International Electrotechnical Commission, will be held under the auspices of the American Institute of Electrical Engineers. Dr. C. P. Steinmetz has accepted the Honorary Presidency of the Congress, and the deliberations will be divided among 12 sections, which will deal exclusively with electricity and electrical practice. There will probably be about 250 papers. The first membership invitations will be issued at an early date.

Attention is drawn to the distinction between this Electrical Congress and the International Engineering Congress which will be held at San Francisco during the week immediately following the Electrical Congress. The Engineering Congress will deal with engineering in a general sense, and electrical engineering will be the subject of one of its 11 sections. It is expected that about 12 papers treating more particularly with applications of electricity in engineering work will be presented before this Section.

The International Electrotechnical Commission will meet during the week preceding the meetings of the Electrical Congress.

16 FEBRUARY, 1914.

No. 228.

SOME RAILWAY CONDITIONS GOVERNING ELECTRIFICATION.

By ROGER T SMITH, Member.

(Paper received 8th January, 1914; read before THE INSTITUTION 12th February, and before the BIRMINGHAM LOCAL SECTION 11th February, 1914.)

Some of the most important and best work done by electrical engineers in this country has been expended on suburban and underground railway electrification. Yet it was not until Volume 51, published last October, that any important contribution on the subject was made to the *Journal* of this Institution. That volume contains a paper by Mr. Lydall on electric locomotives—to be referred to later—and the papers on electric traction which formed the larger portion of the subjects discussed at the Paris meeting of the Institution last May when we were the guests of La Société Internationale des Electriciens.

Circumstances have decreed that up to the present time British electrical engineers have to go to the Continent or to America for examples of railway electrification for other than urban or suburban services. Now that the Institution proposes to have a series of papers on the subject of railway electrification it seems desirable to deal in the first of them with some of the railway conditions in this country which may account for our apparent lack of enterprise. Each country has its own railway conditions and economics, and because main-line electrification is economically sound or experimentally desirable in parts of Europe and the United States it does not follow that it may be equally right for us. The dearth of money and the demands of labour make it at the present time very difficult, if not impossible, for British railways to spend money on experiments on electrification other than on a small scale.

In a country like ours, possessed of a system of steam railways which have cost more to build than railways elsewhere, a third generation of men inheriting the traditions of the past is being trained to work them. It seems reasonable that if any change from steam to electricity is proposed by electrical engineers they should first endeavour to provide something which will at least do what steam will do, next try to give electrically what steam cannot give, and finally do this in such a way as will result in improved financial prosperity to the railway. It is far easier to change things than to change the habits and inherited instincts of large bodies of men, and electrical

engineers have not only to show railway managers that they can haul the railway traffic either better or more cheaply than is done to-day by steam, but that they can first of all haul traffic at least as well as it is hauled by steam, and fulfil most if not all of the functions of the steam locomotive in the manner in which those who work the traffic have been accustomed. Any proposal, otherwise economically correct, that will suddenly alter the way in which large bodies of men have been accustomed to handle traffic in the past is not sound engineering or sound business unless the resulting gain is very considerable.

At the Paris meeting the Institution had the advantage of discussing not only certain applications of electric traction to French railways, but also a reasoned analysis on the position of electric traction on the railways of the United States as it appeared to a French engineer.*

As an outcome of that discussion, and with the view of suggesting some of the things in railway working which steam now does, and are already done or will have to be done as well or better by electricity, it is convenient to divide railway services into three groups. These three groups correspond to entirely different conditions as far as traction is concerned.

1. Urban and suburban passenger services.
2. Fast passenger services.
3. Fast or slow goods and mineral service.

It is not pretended that this exhausts the types of services for which it is profitable to consider electric as compared with steam haulage. For instance, the electrification of terminals is not included, nor incline working, nor the marshalling of passenger and goods trains, nor the working of goods and mineral shunting yards. Shunting conditions only will be referred to later. The above division is sufficient, however, for the purpose of such generalization as is alone attempted in this paper.

* H. PARODI. "Railway Electrification Problems in the United States." *Journal I.E.E.*, vol. 51, p. 526, 1913.

1. URBAN AND SUBURBAN PASSENGER SERVICE.

Urban passenger service.—A purely urban electric service is a thing so much apart, and has been so excellently engineered as far as London is concerned in its underground railways, that it is not necessary to discuss it in any detail here, since it differs only in degree from suburban service. Steam traction for underground services is out of the question in the twentieth century, quite apart from any special advantages that electric traction may possess over steam traction in the matter of services with frequent stops averaging about half a mile apart. All underground passenger haulage must be electric.

Suburban passenger service.—A suburban passenger service exists to enable a working and business population to live outside the town in which it works. In this country suburban transport has mostly grown haphazard with the population and its extent is governed by the time which people consent to spend in the train between their homes and their business occupation. Excluding outer suburban service the limit may be taken to be about 45 minutes each way. The greater the distance covered in that time, that is to say the higher the schedule speed (average speed including stops) of the train the more chance has the railway of creating new traffic.

If a railway possessing a suburban system equipped with permanent way, platform accommodation, and locomotives designed for a certain time-table finds this equipment outgrown by the traffic, it is obvious that it must increase the number of coaches run in a given time. To do this several courses are open.

First, it may double or treble the number of tracks and increase both the number and length of its platforms, thus increasing the number of passengers carried without necessarily increasing the journey schedule time. In the past this has been done on several of the London railways with suburban services, the cost of widening the line and rebuilding the stations having been enormous.

Secondly, the railway may retain its permanent way and stations and with them the maximum length of its trains, but increase their schedule speed by using the biggest type of steam locomotive permitted by the load gauge for running comparatively light suburban trains. This has been worked out and tried experimentally for the Berlin suburban service,* but comparatively little has been done by locomotive engineers in this country to design a steam locomotive purely from the point of view of the rapid acceleration of a light suburban train. It has been done on the Great Western Railway and also in the case of the rail steam auto-car, which, with high adhesive weight, does possess fairly rapid acceleration.

Thirdly, the railway may electrify, which solution is commending itself to many of the railways in this country with congested suburban services. With electrification a maximum of 48 trains an hour can if required be run each way during the rush hours while employing existing stations and tracks. That it is possible to run trains so close to each other is chiefly due to signalling by track circuits, but full advantage of the possibilities of running up to 40 or more trains per hour by the use of

track-circuit signalling can only be taken by trains having rapid acceleration and very rapid deceleration. With tracks and stations (and hence also the train length) remaining as before, the number of passengers carried per hour has in many cases been doubled by increasing the schedule speed 50 per cent, while improved signalling has at the same time made it possible to increase by 50 per cent the maximum number of trains per hour.

The characteristics of urban and suburban services for which electric traction is suitable are a dense or fairly dense service of not less than, say, 5 trains per hour each way, up to 40 and more per hour each way, with station stops varying from less than half a mile apart up to $1\frac{1}{2}$ miles apart. With services less dense than the minimum, and with stops further apart on the average than the maximum here given, the advantages of electric traction, if they exist, are special and not characteristic.

The essential element which gives to electric traction its advantage over steam under these conditions is the motor-coach train. The train is made up either entirely of motor coaches (as in the western suburban system of the French State Railways) or of motor coaches and trailers. The number of motor coaches must be such that the weight on the driving wheels available for adhesion is not less than 25 per cent of the total train weight. It is more often 33 per cent, and may be 100 per cent. The making up and driving of such trains have been rendered possible by multiple-unit control.

With the motor-coach train it is quite easy to have such an adhesive weight as will permit of a tractive effort, over and above that required to haul the train against resistances, sufficient to accelerate it during the notching period at rates up to $1\frac{1}{2}$ miles per hour per second (2.2 ft. per second per second), while the rate of deceleration is usually increased up to 2 miles per hour per second. Such a rate of acceleration is not often justified, and a more characteristic example may be taken from one of the London suburban services where trains weighing 175 tons are accelerated during the notching period at 1.7 ft. per second per second to give with 20-second stops a schedule speed of 17 miles per hour, the station stops averaging half a mile apart. The adhesive weight is 46 per cent of the train weight, and the energy input while accelerating is 1,300 h.p. Within the load gauge of this railway no steam locomotive could be built of such a power. If it could be built it would have (in order to give the necessary adhesion and power) four times the weight of the electrical equipment, which is distributed over 8 axes.

Although belonging more to the economic than the engineering side now under consideration, the cost in energy of such a reasonable acceleration and schedule speed, which is about that of most of the London underground railways, is shown by Fig. 1, representing actual tests of 20 such trains, the rate of acceleration being constant at 1.7 ft. per second per second while the distance between stops varied, giving an average schedule speed over the whole distance of 17 miles per hour. The energy in watt-hours per ton-mile at the train includes the moving and controlling of the train only; brake pumping, lighting, heating, and idle mileage being excluded.

Other advantages of the multiple-unit-controlled motor-coach train, as has often been stated, are first the doubling of terminal accommodation by halving the number of

* Trials have been made on the City and North Circular section of the North Circular Railway of the Berlin City Circular and Suburban Railways with a 2-4-2 and 2-8-2 tank steam locomotive hauling 300-ton trains.

signal and locomotive movements, and secondly the ability to make and break up the motor-car and trailer units of which the maximum train is composed to suit the traffic.

No piece of apparatus is more fitted to accelerate a train rapidly than an electric motor with a series characteristic. The series-parallel connection of the continuous-current motor can give without opening the circuit two running speeds for each definite load after acceleration is complete, while in the single-phase motor voltage regulation can give as many running speeds as are desired.

For any suburban service requiring 20 trains per hour to bring morning passengers in and take evening passengers

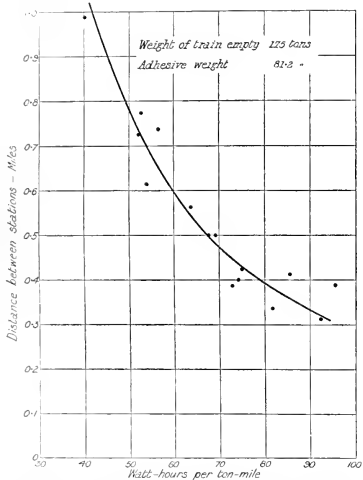

FIG. 1.—Curve of energy consumption for London Suburban Motor-coach Train plotted with distance between stops for a schedule speed of 17 miles per hour. 20-second stops at stations.

out of a city, tracks and terminal accommodation must be set apart exclusively for the purpose. It is not overlooked that two of the most important and successful suburban electric services in this country, namely, the Liverpool suburban services of the Lancashire and Yorkshire Railway and the Newcastle suburban service (if such it may be called) of the North-Eastern Railway, run for some distance over main lines used by steam trains. The maximum number of trains per hour is 12 each way in the case of the Lancashire and Yorkshire service, and 6 each way in the case of the North-Eastern service. The North-Eastern electrification is something more than a suburban system, while the Liverpool-Southport service is a very successful experiment in the creation of new traffic, which makes it typical of the best sort of suburban service.

In general, however, it is safe to say that until it is necessary to devote terminal facilities, station accommodation, and at least two tracks entirely to a suburban service, it is very doubtful if electrification is the only solution of the congested traffic problem, although it may prove to be the best solution. Most of the suburban services into and out of London already electrified or in process of being electrified are run on tracks distinct from the main line, and such a service becomes a thing apart. It can be electrified on any system which best suits its conditions, and the method may be quite different from any other method which may subsequently be desired for main-line electrification.

Under such conditions—and they are exemplified on the largest scale in Europe by the suburban lines leaving the St. Lazare Paris terminus of the Western French State Railway system—the results of suburban electrification all the world over show that there are really no fresh engineering problems to be solved. On both sides of the Atlantic there are numerous examples all more or less on the same lines, two new systems out of London, one north and the other south of the Thames, being now in process of equipment by the London and North-Western Railway and the London and South-Western Railway respectively. Compared with steam haulage the measurements of power are so simple and cheap that when the traffic department asks for any reasonable schedule the engineer is not only able to design his equipment to work to it, but can say within very close limits what it will cost in power and what it will cost in maintenance.

Passing from the engineering to the economic side, the question of the electrification of a suburban system has become for a railway company purely one of finance. Essentially it resolves itself into a question as to whether the fares charged for the service, even with the additional traffic obtained, can give a reasonable return, or any return at all, upon the new and old capital, after the cost of working has been provided for.

When electric tramways were developed in this country for urban and suburban services they competed directly with railway steam services in many large towns. As an example, when London started its electric tramway service on the south side of the river the suburban steam service of the Brighton Railway decreased from 8 million passengers to 5 million passengers per annum. On electrifying its lines not only did the railway regain this loss in the first year, but it has since added to its traffic steadily; at fares, however, lowered by the tramway competition.

It must be remembered that the tramway uses the streets and pays only for its construction, for part of the paving, and for a part or the whole of necessary street widenings. The railway has paid for the land—often acquired compulsorily at an exorbitant price—and has had to put on the land costly permanent way and structures. Usually a railway company is the largest ratepayer in any parish through which it passes, and is often the largest ratepayer in any town. It may therefore be called upon to pay rates to a municipal body on which it is not represented, in order to keep up part of the roads used by a competing tramway. If the municipal tramway is run at a loss the railway helps to pay the losses of a competitor whose presence reduces the railway fares.

The tramway in turn is now menaced by the competition

of the motor omnibus, which pays nothing beyond the petrol tax for its right to use the roads in order to compete with both railway and tramway.

The management of a railway has to decide in each individual case whether, considering its handicap in the cost of its road, which one of its competitors has not to meet at all, and its high rating, which may go to assist the other competitor, it can make enough money out of competitive fares to justify the added cost of electrification.

Even when it cannot make the development of its suburban traffic pay directly it may still pay the railway as a whole considered only as a feeder to the main line, or urban and suburban traffic as a whole may pay if the latter goes far enough out into the country. This latter type of suburban service is best illustrated by the Liverpool-Southport electrified system on the Lancashire and Yorkshire Railway.

From Liverpool to Hall-road, $7\frac{1}{2}$ miles away, the average distance between stops is $\frac{3}{4}$ mile and the schedule speed is above 25 miles per hour. This is probably the most rapid suburban service in existence. From Liverpool to Southport is 18½ miles, with an average distance between stops of 1½ miles, but beyond Hall-road this average is only a little under 2 miles. The schedule speed of stopping trains is 30 miles per hour. The maximum instantaneous input to the train is nearly 2,000 h.p., and the power consumption for the stopping trains to Hall-road is about three times the power averaged over the whole service of stopping and express trains and idle mileage. This is an excellent example of how a service if extended far enough out and combining express with stopping trains reduces the energy used over the whole system to a reasonable figure. The long-distance fares have to make up for the far greater cost of the short-distance stopping service.

Not only have electrical engineers completely solved the engineering problem of frequent service with short distances between stops, but the cheap and simple measurements of electrical quantities have taught railway companies for the first time how costly the constant stopping and starting of a train must be as compared with running at high speeds with infrequent stops, whatever form of power is used for traction.

It is not that suburban electric traction costs an unreasonable amount, but that circumstances make the revenue from such services unremunerative. Suburban fares have been falling steadily, and at the present moment it is safe to say that everybody in London and its suburbs is being carried at too low a fare to give proper remuneration to any form of traction which, in addition to rates and taxes and government duty on some fares, pays for its road and the right to use it.

From the report of the London Traffic Branch of the Board of Trade for 1912, particulars of London urban and suburban traffic can be obtained and compared with the returns and estimates of the omnibus and tramway traffic. From these returns it appears that if the suburban systems of the main-line railways running into London are left out of account there has on the whole been no increase during the last three years in the number of passengers carried by the underground railways of London, all of which are electric. Quite considerable increases have taken place in some lines—the District

carried 7½ per cent more passengers in 1912 than in the previous year—but other lines lost some of their passenger traffic, and the total number remains stationary at about 436,000,000 passengers per annum. The average fare was a trifle above 1d. The purely London traffic of the main-line railways—inclusive of their suburban traffic—is estimated for 1912 as 250,000,000, which is a decrease of 1½ per cent on the traffic of the previous year.

The London tramway traffic in 1912 is estimated at 800,000,000, which is a decrease of 3 per cent on that of the previous year, while the omnibus traffic amounted to 550,000,000, or an increase of 37 per cent on the 1911 figures. Greater London traffic as a whole increased by 125,000,000 passengers in the same period, which is 20 per cent less than the omnibus increase, every other form of traffic having declined except that on the underground railways, which remained stationary.

A Parliamentary Committee has been investigating the problem of the city, circular, and suburban services in Berlin, and it reported at the end of 1912. Fares have been reduced to such an extent that in that year they averaged 3d. per passenger, or half the average unremunerative fare in London. With steam traction these fares do not pay working expenses, and no capital charges whatever have been paid of late years on about £12,000,000 spent on the Berlin railways.

In 1913 money was voted for the electrification of the city and circular railways, but the suburban electrification is not to be dealt with at present. The point of interest is that, after electrification, fares all round are going to be raised to such a figure as will not only pay working expenses but capital charges (interest and amortization) on the old and new capital.

Like most other industrial working costs, that of running a suburban service depends on certain standing charges which taken as a whole do not vary, or hardly vary, with the service given (upkeep of permanent-way equipment, management, rent, rates and taxes, and station traffic expenses) and a charge varying with the service catered for (rolling-stock repairs and wages, running wages and electricity). In a particular case the ratio of standing to variable charges for running a small suburban service for a year was as follows: Standing charges unaffected by the number of trains 60 per cent, variable charges 40 per cent, and of this 40 per cent electricity formed three-fourths.

If the cost of electricity can be reduced by 50 per cent the total working costs may be reduced by one-quarter, which shows the importance of cheap electricity. This is a particular case where the cost of electricity was high, and as a rule its percentage effect is not so great.

Fig. 1 shows how, for a given average schedule speed, the distance between stops affects the amount of electricity used, and supposing it were possible to have a differential tariff for railway passengers based on the actual cost of the service, the short-distance passenger ought to pay much more per mile than the long-distance passenger, since he costs more to carry; but on nearly all suburban services competition has cut down the fares of the short-distance passenger to a non-profitable point.

What is wanted to make urban traffic on electrical lines pay is either an increase in the fares, which is achieved abroad by zone fares, or the ability to purchase electrical energy delivered to the conductors at say 3d. per

kilowatt-hour. Competition may prevent the former. Is there any chance of obtaining cheaper electricity?

The generation of electrical energy and its supply is a business in itself. In many cases it has not in the past been possible for railways electrifying suburban services to buy electricity from outside,² but wherever they have been able to do so the saving of the initial cost on which capital charges have to be met and the saving to the railway of the management of a business organization that is very different from its other organizations are a great gain. In general the addition of a load which in the case of a heavy suburban service may continue during 18 or 20 hours out of the 24 with an annual maximum demand load factor of from 45 to 55 per cent, should enable a supply authority with a light and power load to offer a railway company such a price as would leave no question as to its acceptance. It is scarcely necessary to point out, however, that the purchase of electrical energy has not been the policy of the majority of the railway companies. Some of them have had no chance of buying, but those like the North-Eastern and London, Brighton and South Coast Railways who have purchased electrical energy have no reason to regret it.

To sum up the situation with regard to suburban electrification as it appears to the author, the electrical engineer is in a position to inform his railway very exactly what the initial and working cost will be. The management have to decide what the financial result will be with the existing and expected traffic, which has to pay working and capital charges on the new capital before earning a dividend on the old. Competitive fares are so low that the process is generally discouraging except where a new traffic can be created in districts from 10 to 30 miles from the terminus. The cost of electric working is important, but as Mr. Insull has recently pointed out the cost of money may be still more important, and the raising of fresh capital for anything that is not certain to swell the dividend is a very serious matter indeed at the present time when the credit of British railways stands so low.

2. FAST PASSENGER SERVICE.

When the condition of frequent stops and short distances between them is left and the question of main-line passenger services as run by steam locomotives is considered from the point of view of electric traction, the problem alters completely.

To give some idea of the effect of stops it may be mentioned that in a particular steam service a 7-coach train weighing 187 tons, including a dynamometer car, required an average draw-bar horse-power of 277 when hauled by a steam locomotive at an average schedule speed, including stops, of 40 miles per hour, the stops on a nearly level road being 23½ miles apart. The same train, run at an average schedule speed of 27 miles per hour and stopping on the average every 5½ miles, required an average draw-bar horse-power of 284, or practically the same. The time taken to do the same distance is in the ratio of 1 to 1½, so that the energy used for the stopping service for the same distance is 50 per cent greater than for the fast service. The condition of the track, wind, and weather make such great differences in the power, that any generalization from

² See Chairman's address to the Newcastle Local Section, *Journal I.E.E.*, vol. 52, p. 17, 1914.

individual tests is dangerous, and such tests are too costly to be made often; but such an instance will serve to indicate how increasing fourfold the number of stops in a given distance makes the cost of hauling a slow train much greater than the cost of a moderately fast service with few stops.

A good deal of experimental and pioneer work has been done on the Continent and in the United States in electric locomotive design, but the engineering problems which have to be solved in this country before fast passenger electric services can compete with existing services have hardly been considered.

In a paper such as this, only intended as a preface to more detailed papers and to stimulate discussion, it is

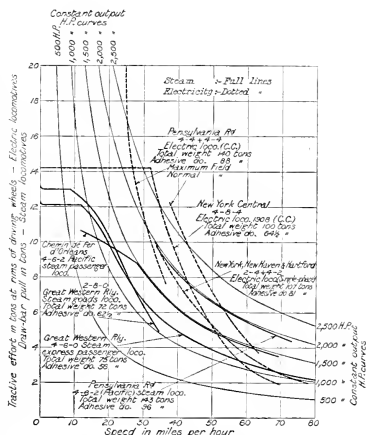

Fig. 2.—Curves of maximum continuous draw-bar pull (steam locomotive) and maximum tractive effort at driving-wheel rims (electric locomotive) plotted against speed.

impossible to do more than touch in general terms on some of the difficulties; but those interested are referred to two papers³ read before the American Institute of Electrical Engineers last May, where a very useful method of analysis is developed and many constants given for comparison between steam and electric working. The discussion is, it must be remembered, purely on American practice where traffic conditions are entirely different from those in this country, but the principles of the analyses are the same for all countries.

The chief difficulty in the way of electrification for fast passenger services is the existence of the steam locomotive. Fig. 2 gives curves kindly supplied to me by Mr. G. J.

³ H. M. HOBART, "2,400-volt Railway Electrification," *Proceedings of the American Institute of Electrical Engineers*, vol. 32, p. 1015, 1913.

C. P. KAHLER, "Trunk Line Electrification," *Ibid.*, vol. 32, p. 1057, 1913.

Churchward, of draw-bar pull plotted against the speed for two types of steam locomotives, one for passenger service (the 4-6-0 type*) and one for goods service (the 2-8-0 type). The curves represent the average results for saturated steam of many experiments with each type of locomotive hauling actual trains, the draw-bar pull being measured by the dynamometer car. The two types of locomotives may be taken as representative, one for hauling fast passenger trains and the other for hauling fast goods trains with nearly the maximum loading on the coupled axles permissible for British way and structures. They also represent approximately the maximum powers which can be developed by steam locomotives built within British load gauges, which are not the same for all our railways. Constant-output draw-bar horse-power curves are added for guidance. Curves of an American and of a French steam locomotive of the 4-6-2 or Pacific type are added for comparison.

The steam locomotive is so designed that with earlier and earlier cut-off as the speed increases, practically constant outputs are obtained for the same load. The time-tables of British railways imply maximum speeds of between 70 and 80 miles per hour. The resistances to train movement increase in proportion to the speed raised to the $\frac{3}{2}$ power, so that for trains running with infrequent stops a locomotive with constant output has sufficient reserve of power at low speeds, over and above that required to overcome resistances, to give a moderate acceleration (up to the limit imposed by the adhesion of the coupled wheels) and to maintain the train at any speed (determined by the regulator and the cut-off) up to the maximum speed with that load.

To all interested in this problem Professor Dalby's paper† on dynamical diagrams of the motion of a train is recommended.

As compared with the electric locomotive the steam locomotive is handicapped by the distribution of weight due to the length of the boiler. In the former, from the shape and size of the motors it is possible to get a greater ratio of adhesive to total weight than in the latter, especially if every axle is driven. In general for fast passenger service the acceleration of the steam locomotive is limited not only by the boiler capacity but by the maximum adhesive weight on the coupled driving wheels.

For the 4-6-0 type locomotive, the adhesive weight being absolutely limited by structures to 60 tons, and by usual practice to 50 tons, the starting draw-bar effort is limited to about 16 tons. From the start until the driving wheels are moving at about 50 revs. per minute—say about 12 miles per hour for the engine under discussion—the maximum draw-bar pull is 12 tons, determined by the adhesion.

Such a passenger engine can haul a train of 450 tons on the level at the highest speeds called for in this country

and, unassisted, a train of 300 tons up a gradient of 1 in 50. The maximum length of the train is in general limited by the minimum length of the station platforms, and without radical changes in station structures no heavier trains can be run except for occasional "rush" traffic. To haul such a train, a constant-output locomotive is satisfactory, and the control of the output and speed by the regulator and the cut-off is so complete that the steam locomotive can run at any speed below its upper limit for the load hauled.

With the exception of certain three-phase locomotives in Italy and America, all the electric locomotives built have been equipped with motors having series characteristics. At any given voltage the series motor has one speed for each definite load. Series-parallel control with continuous-current motors gives two speeds, and with certain numbers of motors three speeds for continuous working can be obtained.

The problem of getting the adhesion necessary to prevent the slipping of the wheels when starting is, in general, possible with appreciably lower axle loads than for the steam locomotive, while for the same tractive effort the advantage in total weight is always in favour of the electric locomotive. Since the series motor can be overloaded momentarily 75 per cent above its hourly rated capacity, while for adhesion purposes if necessary every axle can be made a driving axle, even greater starting torques than those shown in Fig. 2 are possible, but on British railways they would be not only useless but actually harmful, exceeding the draw-gear strength. Unlike the case of the multiple-unit train, the adhesive weight may be only 12 or 14 per cent of the total train weight, and the strength of the draw-gear limits the draw-bar pull after starting to 12 tons. But with an increase in speed the torque of the series motor falls off so rapidly that above 60 miles per hour (where difficulties begin with steam locomotive design) no electric locomotive yet built for hauling only such maximum loads as obtain on our railways could give anything like 1,100 h.p. at 70 miles per hour, as given by the 4-6-0 steam locomotive shown in Fig. 2.

Fig. 2 shows tractive effort curves of a few fairly modern American electric locomotives, the loads representing not draw-bar pull but tractive effort at the rims of the driving wheels, so that the hauling of the locomotive itself is included. They are added to show how very quickly the tractive effort at the rims of the wheels falls off at high speeds. Such locomotives are only of academic interest to us, as their starting effort is quite beyond the strength of draw-gear on British railway passenger stock.

Very valuable information on the performance of modern electric locomotives is given in Mr. Lydall's paper communicated to this Institution,* both in the table of particulars and in the text, but it will be noted that with the exception of the two locomotives of the 4-4-2 type (Mr. Lydall's 2-B-1) and the 2-6-2 type (Mr. Lydall's 1-C-1) with maximum tractive efforts less than half that of a 4-6-0 steam locomotive none are intended to run at speeds of 70 miles per hour or over, which is required for fast passenger service in this country.

Mr. Lydall, on p. 747, lays down the requirements for a fast passenger locomotive capable of giving a draw-bar pull of 10 tons at 40 miles per hour and $3\frac{1}{4}$ tons at 75 miles per

* F. LYDALL. "Electric Locomotives." *Journal I.E.E.*, vol. 51, p. 739, 1913.

* There is no uniformity in different countries in the symbols used for types of locomotives. This paper follows American and British steam practice, thus 4-6-0 indicating a leading 4-wheeled bogie, 6 coupled driving wheels and no trailing pony or bogie, 2-8-0 indicates a 2-wheeled leading pony, 8 coupled driving wheels and no trailing pony or bogie, 4-4-4-4-0 indicates an articulated locomotive with leading and trailing bogies and 4 driving wheels in each half.

† W. E. DALBY. "Characteristic Dynamical Diagrams for the Motion of a Train during the Accelerating and Retarding Periods." *Proceedings of the Institution of Mechanical Engineers*, Parts 3-4, p. 877, 1912.

hour. If such a locomotive could be built it would more than meet the case at the maximum speed, but with series characteristic motors its curve of draw-bar pull plotted against speed would not be quite like any of the curves in Fig. 2, and it would develop nearly 2,500 h.p. at 40 miles per hour, and more at starting. Such locomotives would entirely alter the conditions under which British passenger traffic is worked.

One object of the series winding is to saturate the field of the electric motor at starting, and provided the field is saturated no extra current through the winding is of any use. The field can equally well be saturated by separate excitation, which opens out the possibility of a shunt characteristic with variable speed for the continuous-current motor, voltage variation already providing several running speeds with the single-phase motor.

The very interesting experimental line equipped by the Lancashire and Yorkshire Railway for 3,500-volt continuous-current electrical working between Bury and Holcombe Bridge has two motors on its motor coaches permanently in series and a motor-generator for providing current at 100 volts for the auxiliary service of control, brake pump, lighting, and heating. The same principle could be used for exciting the field, and it is suggested that such a method of obtaining the series characteristic at starting and the shunt characteristic for higher speeds is worthy of consideration.

The two Prussian State Railway locomotives already referred to are both single-phase locomotives working the driving wheels through connecting rods, and come much nearer to Mr. Lydall's idea for fast passenger service than any other type; but they do not reach it, and it seems fair to say that up to the present time no electric locomotive has been made suited to our maximum loads which can replace the fast passenger steam locomotive in this country.

Turning from the engineering to the economic side, and assuming a suitable electric locomotive has been built, a very rough estimate may be made of the cost of working, more with the purpose of showing the direction in which economies are desirable than of giving any figure that can be used for estimating purposes.

The annual cost of a steam passenger locomotive, averaged over all the different types in use on a railway carrying passengers, goods, and minerals over not less than 2,000 miles of route, and hauling its own locomotive coal, may be taken to be £825 for such items as do not vary with the mileage run or only vary to an extent which will not affect this first approximation. These include capital charges (which are taken at 6 per cent for interest and obsolescence), administration and management, wages of drivers and firemen, oil and small stores, maintenance repairs and renewals. To this is to be added the cost of coal and water, varying more or less directly with the mileage, which for passenger service may be conveniently taken as the train mileage. The annual cost of coal at about 9s. per ton per 10,000 B.Th.U. averaged over the whole working together with the cost of water may be taken to be £350, giving a total for the year of £1,175 inclusive of capital charges. This is a mean for all locomotive types working an average passenger mileage of 10,000,000 train-miles per 1,000 miles of route. During the year a passenger engine may be expected to run

between 25,000 and 30,000, or say 27,000, passenger train-miles, so that the mean cost for locomotive expenses (including locomotive capital charges) per train-mile will be 10½d.

Of the above sum of 10½d. per train-mile 3d. per train-mile will represent the cost of coal and water. After the coal strike in 1912 the cost per ton went up 2s., but neglecting its present high but fluctuating value, and taking the cost of the best English coal used at 12s. 6d. per ton, to which 3d. per train-mile corresponds, cheap coal in this country is one of the factors making against railway electrification. The cost of coal burnt in a large modern generating station producing electricity for hauling trains by an electric locomotive is less than half the cost of coal for doing the same work in a steam locomotive. In America coal costs about the same as in England, but in France the 3d. per train-mile for coal and water would be at least 6d., and in Switzerland and Italy 9d. or more. The influence of the cost of steam locomotive coal in non-coal-producing countries, more especially where water power is available for generating electricity, becomes obvious from this form of analysis without claiming any great exactitude for the actual figures given.

In the paper on 2,400-volt electrification already referred to, Mr. Hobart* works out the efficiency of a Pacific type 4-6-2 steam locomotive between the heat value in the coal in the tender and the work done at the draw-bar, and correcting his constants for the results obtained with the largest modern English locomotives using coal of a calorific value of about 15,000 B.Th.U. per lb., the value of this efficiency is 34 per cent. Allowance is made in this figure for the coal used in firing up and remaining in the firebox at the end of the journey. He also quotes the actual efficiencies obtained between the heat value in the coal in the bunkers of a large modern electric generating station using similar coal and the work done at the draw-bar of an electric locomotive for similar work, and finds it to be 6 per cent after his constants have been altered to suit English conditions. Working from these efficiencies the result is obtained that the cost of electricity per passenger train-mile is about the same as the cost of coal and water per passenger train-mile hauled by the steam locomotive, provided that electricity can be bought at ½d. per kilowatt-hour.

Weight for weight the electric locomotive costs about twice as much as the steam locomotive, but for the same adhesive weight the electric locomotive weighs some 30 to 40 per cent less than the steam locomotive. Electric repairs and renewals cost less, and the net result is that the annual cost of the electric locomotive will be in the neighbourhood of £1,250 per annum, assuming the same rate for capital charges.

But while the passenger steam locomotive only runs on the average 27,000 train-miles in the year, spending 75 per cent of the time out of active service, the electric locomotive, which need only be in the shops for one month out of the 12, will not spend more than 50 per cent of its time out of active service. The electric locomotive can run at least 40,000 passenger train-miles per annum. There is not much experience to go on, and that experience has been wholly obtained in other countries. The suburban working in London where electric locomotives are used is so restricted that no figures are obtainable which can

* *Ante*, p. 297.

be compared with steam working. Multiple-unit motor-cars run 45,000 to 50,000 miles per annum.

If these figures are accepted, the cost per train-mile with the electric locomotive (including locomotive capital charges) will be 7½d., always assuming that electrical energy can be bought at ½d. per kilowatt-hour.

It must again be emphasized that these figures can only be considered as a first approximation to the truth, and they will differ for different railways. But assuming that for a railway running 10,000,000 passenger train-miles per 1,000 miles of route, the conditions enabled electric locomotives to run 40,000 miles annually, so that a saving of 3d. per train-mile was secured by electrification, there would be a possible annual saving due to electrical working of £125,000. If capital charges (interest and amortization) were 6 per cent, this would represent the charges on a capital of £2,100,000 per 1,000 miles of route, or £2,100 per mile of route. This sum would certainly not cover the corresponding electrical equipment of the line on an overhead system, inclusive of contact wire and structures, distributing cables, bonding, and sub-stations.

The only items for which a reduction in costs may be expected are the cost of electricity and the capital cost of electric locomotives. No great reduction in the cost of the former can be expected so long as railways generate their own electrical energy, as there must be a diversity of load and generation on a scale far beyond railway requirements to secure an appreciable reduction in price. If electrical energy could be bought at ½d. per kilowatt-hour, and the electric locomotive could be made for £50 per ton, the cost per train-mile in the above estimate would be reduced to about 6d.

The problems in front of the electrical engineer who would compete with the passenger steam locomotive are therefore first to design an electric locomotive that will do what the steam locomotive does at high speeds; secondly, to reduce the cost of the electric locomotive (which will come about when there is sufficient demand for it); and thirdly, to be in a position to buy electrical energy at something approaching the ½d. per kilowatt-hour which forms Dr. Ferranti's ideal.

3. FAST OR SLOW GOODS AND MINERAL SERVICE.

Reference has already been made to Mr. Lydall's paper on electric locomotives, and his proposals for a fast passenger locomotive. Two types are also suggested by Mr. Lydall for goods locomotives,* one to give a draw-bar pull of 12½ tons at 17½ miles per hour and 4 tons at 25 miles per hour, and the other to give 12½ tons at 25 miles per hour. Both are to be able to run light at 40 to 45 miles per hour.

Reference to Fig. 2 will show that the 2—8—0 steam locomotive can fulfil conditions about midway between the two. Adhesion would allow of a 20-ton pull at starting, the weight on the coupled wheels being 62½ tons, and when the locomotive is moving and up to about 8½ miles per hour the pull is 13 tons.

For a fast passenger service in this country it has been argued that to compete with steam a suitable electric locomotive has yet to be designed and made for about half its present cost, while it must use electricity at rates not yet in view.

For goods and mineral service the outlook is different, and in consequence the form of analysis from averages which was admissible to prove a negative is not admissible to prove a positive. For goods and mineral services each individual case must be worked out on its merits. It may, however, be said that if the same analysis be followed out in the case of the average cost of an electric locomotive for goods working as has been done for passenger working, the same comparative ratio of cost between coal and electricity per train-mile would hold with electricity at ½d. per kilowatt-hour—the price at which it can in some cases be obtained to-day—in place of the ½d. per kilowatt-hour assumed for passenger service.

Complete analyses on different lines have recently been made for American conditions in the papers already cited by Messrs. Hobart† and Kahler‡ with favourable results, and by Mr. A. H. Babcock§ with unfavourable results for mountain-grade electrification. The methods of analysis are well worth study by all interested.

Considering English conditions the chief difference between goods service and passenger service is the reduction in the annual train mileage run by the steam locomotive. Whereas for steam passenger service it was taken to average 27,000, for goods and mineral service it drops to 10,000 train-miles per locomotive. In addition to this the coal per train-mile is nearly doubled.

On the average some two-thirds of the available steam locomotives may be expected to be in steam on any one day, and of those engines in steam the engine mileage will probably exceed the passenger train mileage by little more than 5 per cent. On the other hand goods engine mileage may exceed goods train mileage by more than 30 per cent owing to the many services that the locomotive has to perform other than moving trains from station to station. Each goods engine in steam may not work more than 40 to 50 train-miles per day averaged throughout the year, which gives some idea of the length of time the locomotive is standing in steam and using coal but earning nothing, while nearly one-third of the engines are away under repairs.

It is in this direction that the electric locomotive appears to have its best chance. In America it has been found to be possible at least to double the daily mileage run by a steam locomotive, owing to the ability of the electric locomotive to haul heavy loads at an increased speed while it wastes no energy when standing idle. Instead of more than 30 per cent of the steam locomotive year being occupied in repairs, not more than 10 per cent of the electric locomotive year need be spent in the repair shops.

Fig. 2 shows the available tractive efforts of one or two electric locomotives in America at low speeds, but American conditions are not our conditions, and a locomotive giving a starting pull much greater than the 2—8—0 steam locomotive is of no use for goods service in this country. In America the strength of the draw-gear is such that draw-bar pulls of more than 30 tons are permissible, and trains of 3,500 and 4,000 tons weight can be hauled if fitted with continuous brakes. In British goods and mineral service the limiting factor is the strength of the draw-gear,

* *Proceedings of the American Institute of Electrical Engineers*, vol. 32, p. 1015, 1913.

† *Ibid.*, vol. 32, p. 1057, 1913.

‡ *Ibid.*, vol. 32, p. 1783, 1913.

* *Journal I.E.E.*, vol. 51, p. 749, 1913.

which is tested to 50 tons and with a factor of safety of 4 is supposed to be worked at a maximum load of 12 tons.

English railways started by hauling vehicles belonging to the public, and they have never ceased to do so. At the present time it is estimated that there are some 700,000 wagons^{*} owned by traders liable to be run on British railways. They are built to specifications which have been issued from time to time by the Railway Clearing House, but draw-gear starts to deteriorate from the time it is first put into service.

On lines with no adverse gradients it is possible at times to haul trains of 100 wagons weighing 1,600 tons, but that is the exception in this country. Goods trains of 56 wagons weighing 900 tons can be taken by a 2-8-0 engine up gradients of 1 in 150, and of 24 wagons weighing 380 tons up gradients of 1 in 50, without endangering the draw-gear, and as a general rule longer trains than 60 wagons are not conveniently dealt with in the usual lay-by sidings, although trains of 100 wagons can be handled in suitable places. We are not, therefore, really limited in our train weights by the maximum size of steam locomotive which can be built within the restricted British load gauges (restricted, that is to say, as compared with America and many European countries), but by the strength of draw-gear and the lay-out of sidings.

While the wagons owned by railways can have their draw-gear maintained against inevitable degradation by fatigue and wear, the privately-owned wagon is not in the same position. Unless the whole method of working goods traffic in this country is to be altered, a locomotive is not required to give a draw-bar pull of more than 12 to 14 tons after starting, and even then the failures of draw-gear will always be considerable with the shocks when starting a loose-coupled train and with the stresses due to unequal braking. A large number of goods and mineral wagons are still loose-coupled. This reduces the necessary starting pull, but at the same time makes it essential that this pull should be increased gradually or the shock on successive coupling chains will break them. The draw-bar pulls of the American electric locomotive shown in Fig. 2 if used on a British goods or mineral train would merely break the couplings.

One class of traffic in this country is happily free from this drawback, and that is the mineral traffic of the North-Eastern Railway on the north-east coast. The railway owns the coal and ore wagons, or the greater proportion of them, and not being handicapped by traders' wagons can maintain their draw-gear at the required standard. They are fortunately situated for the bulk of their heavy mineral traffic in a district served by the North-East Coast electric power companies, and can buy electricity cheaply.

The mineral line between Shildon and Newport (Middesbrough), a distance of 18 miles, is now in process of being electrified, the length of single track and sidings amounting to 50 miles. Two sub-stations on the route will supply continuous current at 1,500 volts, for the most part through overhead conductors and through a protected conductor rail in places where an overhead conductor is inconvenient.

The locomotives will be able to start and haul mineral

trains weighing 1,400 tons at a speed of 25 miles per hour on the level, and start an 800-ton train on a grade of 1 in 100.

Apart from suburban electrification this is the most interesting railway electrification which has been contemplated in this country, and if successful it will undoubtedly be the real beginning of goods electrification. Its working this year will be a matter of great interest to electrical and railway men.

While the cost of everything in the industrial world has been going up, increasing the expense of many things that a railway has to buy, including labour, the railways have not hitherto been able to increase the price at which they sell transport. In passenger service not only have working expenses increased in harmony with the general rise in prices, but the railways are constantly being required to improve their services by providing increased comfort, lighting, and heating, as well as by the provision of restaurant and sleeping cars (which increase the weight hauled out of all proportion to the increase in the number of passengers), and by the speeding up of the trains. Third-class passengers form about 95 per cent of the total number of passengers carried, and as an indirect result of the so-called Cheap Trains Act of 1883 third-class single fares have been fixed at a maximum of 1d. per mile. Therefore, however much expenses may increase, practically no corresponding increase in the revenue from passengers can follow; and it is largely for this reason that the substitution of the electric locomotive for the steam locomotive can only be considered if the result is going to reduce the ratio of expenses to gross receipts by such an amount as will increase dividends.

Rates for goods and minerals are somewhat different. By the Railway and Canal Traffic Act of 1894, in order to increase a rate within the maximum which has been fixed by Parliament the railway must, if challenged, prove before the Railway Commissioners that the increase is reasonable. Even if a rate is lowered experimentally to assist some new form of traffic, it cannot afterwards be raised to some figure below the parliamentary maximum when the business can afford it without the liability of an application to the Railway Commissioners, when the onus of proof would be upon the railway. It has generally been held that the latter could only succeed by showing a proportionate increase in expenses since the lowering of the rate. This liability has undoubtedly worked to prevent the lowering of rates. By the Railway and Canal Traffic Act of 1913, passed as a result of the railway strike of 1911, a reasonable increase in rates is to be allowed within the legal maximum where the railway can prove before the Commissioners that the increase is intended entirely to meet the rise in wages since August, 1911, the date of the strike. The fact that for a portion of its increased expenditure—although under very special circumstances—a railway has been treated as a commercial undertaking, is distinctly hopeful for electric traction, since it tends to remove one element that makes the raising of fresh capital for railways so difficult.

The methods of electrification available for the consideration of the engineer are varied,[†] but for goods working involving the equipment of sidings some form of overhead equipment seems imperative. Continuous current, single-

* In the discussion on M. Parodi's paper at the Paris Meeting in May, 1913 (*Journal I.E.E.*, vol. 51, p. 613, 1913), this figure was given as 500,000, and is here corrected from further information.

† See Dr. Gilbert Kapp's address as President of Section G at the British Association's Birmingham meeting, 1913.

phase with commutator motors, single-phase with split-phase motors, and single-phase with mercury arc rectifiers and continuous-current motors, and three-phase with induction or cascade motors, are all possibilities, and each has to be considered on its merits. It is not within the scope of this paper to discuss systems, but it may be pointed out that owing to the special conditions of goods and mineral traffic in this country—a few of which have been referred to in this paper—the electrification of goods and mineral lines is likely to begin only in favourable districts, especially with steep grades where the overload capacity of the electric motor and its accelerating ability will enable traffic which is now very slow to be speeded up. This will increase the earning capacity of the existing permanent way without costly re-grading.

The electric shunting engine is a very good example of what has to be done in the matter of suitable design. A shunting engine may be called upon for hours to push heavy trains of wagons at 2 or 3 miles per hour and then to clear away a train of empties at 25 miles per hour. It is frequently called upon to push or pull a heavy loaded train over a weighbridge with a pause long enough for the weight to be recorded while each wagon is on the bridge. This the steam locomotive can do, but the continuous-current series-motor locomotive with continuously rated resistances seems hardly an engineering competitor of the steam locomotive for such work as this. There is far more hope for the single-phase locomotive.

To sum up the position as it appears to the author—the inherent advantages of the electric locomotive for goods and mineral haulage are, first, its ability to haul up to the maximum strength of the draw-gear at more than double the speed possible with the most powerful steam locomotive which can be built within British load gauges; secondly, the ability if necessary to have all axles driven, so that the whole weight of the locomotive is available for adhesion while the weight per axle is sensibly reduced; thirdly, the advantage that any driver can work any locomotive, which is not the practice in this country with steam locomotives; fourthly, the ability to run annually at least twice as many train-miles as the steam locomotive, partly due to increased speed and partly due to less time spent in the repair shops and for cleaning; fifthly, the saving of all coal wasted by the steam locomotive when getting up steam, standing in steam, and left in the firebox at the journey's end, with the result that with electrical energy at 3d. per kilowatt-hour the bill for current per mile is about the same as the bill for coal and water per mile; sixthly, the possibility when the strength of the draw-gear permits of loads being hauled quite beyond the capacity of any steam locomotive that can be built within our load gauges. The electric locomotive takes its power from a generating station and not from a moving boiler; it can therefore be designed to give its maximum draw-bar pull at any desired speed. It is for the electrical engineer to make the most of such advantages.

DISCUSSION ON

"BRITISH PRACTICE IN THE CONSTRUCTION OF HIGH-TENSION OVERHEAD TRANSMISSION LINES." *

NEWCASTLE LOCAL SECTION, 12TH JANUARY, 1914.

Mr. Hunter.

Mr. P. V. HUNTER: The author commences his paper by considering when overhead lines are justified as compared with underground cable systems, and gives a comparison of capital costs for various voltages which clearly indicates that the higher the pressure the greater is the advantage that overhead lines possess. Personally, I think overhead lines should not have so much advantage as that shown in the paper. I think the price given for 11,000- and 20,000-volt cables can be substantially reduced. With present standards, cables have a factor of safety which is unnecessarily conservative. For instance, standard 11,000-volt cables could quite properly be used for 20,000-volt working, with a consequent modification in the price from £2,100 to £1,550. I notice at the end of the paper that the author suggests the formation of a Committee for the standardization of transmission lines, but I sincerely hope it will not be formed until a great deal more experience has been obtained, as I attribute the high cost of underground cables to the standards having been settled too early and to the delay in revision. The ques-

tion of factors of safety is referred to on page 179; I am sure that everybody engaged on the construction and operation of overhead lines will agree with what the author has said, and I am of the opinion that Mr. Trotter has been well advised in recommending the factors of safety which have been adopted by the Board of Trade. A point in which I am much interested is protection against atmospheric disturbances. Opinion is, I think, leaning towards the view that tens of thousands of pounds have been wasted on useless (not to say harmful) forms of lightning arresters. I have no faith in the horn-gap, nor indeed in any apparatus which introduces an air-gap in the path of a discharge. In connection with this I think the air-gap in series with the electrolytic arrester militates very much against its satisfactory operation. From experience of these arresters I am not able to say that they are satisfactory as at present used. The form of apparatus which is suggested by the author is the Mosceicki condenser. In so far as it dispenses with a spark-gap I think it must be an improvement on other types. It, however,

Mr. Hunt

* Paper by Mr. B. Welbourn (see pp. 177 and 217).

inter. it is assumed that the function of an arrester is to dissipate the energy of a surge I am afraid the apparatus would become very large and expensive if it had really serious work to do. The author refers to the practice in this district of dispensing with ordinary arresters and protecting the end-turns of transformers. This method was not originated for pole-line work, but was in use long before pole lines were adopted. I do not believe that the transformer has much to do with the matter. The energy of the surge is, I think, dissipated in the cable dielectric, and for this purpose every overhead line is run underground for a short distance before entering a sub-station. Overhead lines have no dielectric hysteresis, as the dielectric is air, assuming of course that the working pressure is below the corona limit. A length of underground cable in an overhead line may from this point of view be regarded as an improvement rather than otherwise. There is, however, no doubt that the insulation at the junction between the overhead line and cable must be liberal. If this is carefully attended to, lightning (other than direct lightning strokes) and surges should give no serious trouble in this country. The author also refers to the pressures which may occur on bare telephone lines from various causes; but he has not mentioned what I think is perhaps the most important case, namely, when a wire breaks and falls to the ground and the currents are no longer balanced in the conductors. This produces a dangerous voltage on the telephone line just at the time when it is most wanted for use. Bare telephone wires on overhead lines should be entirely prohibited.

Reference has also been made to the Merz-Price and Merz-Hunter protective systems and the time taken to operate them, but the figures given in the paper refer to the relay and not the switch, as the former owing to the mass of moving parts does not operate so quickly. Switches are now being made by at least three manufacturers to break circuit in $1/20$ second. This figure is not so small as that given by Mr. Welbourn, but even when added to the time taken for the relay to operate it is quite sufficient to prevent a live wire touching the ground, assuming of course that the relay is of a type that begins to operate immediately the wire breaks.

Mr. F. O. HUNT: The author refers in his paper to the time taken for automatic switches to open the circuit as $1/80$ second, but I am glad to learn from Mr. Hunter that this refers to the relay and $1/20$ second to the main switch. The important matter is the combined time of the two; for if this can with certainty be brought well within the time taken by the fall of a wire, there is a very strong probability that the operation will be over before the wire could reach a human being. This has an obvious bearing upon the height at which conductors should be placed above places where men may occasionally have to work. The chief difficulty lies in the great mass of the current-carrying and mechanical parts of switches for high power. This mass involves correspondingly great forces in order to bring about sufficiently rapid acceleration; yet in the process of closing the switch these forces have usually to be overcome by hand operation. It is necessary to aim in design at lightness, even of the balanced parts, in order to keep down the total moment of inertia. The use of cable telephone systems seems perfectly sound practice, but I should be glad to know whether any trouble has been

experienced with regard to the distance over which it is Mr. Hunt possible to speak under these conditions.

Mr. J. R. M. ELLIOTT: I am afraid that I cannot speak Mr. Elliott with any practical knowledge of the building of heavy power lines, my experience having been confined to the construction of telegraph lines, but there are several points to which I should like to refer. Touching on the statutory powers possessed by the Postmaster-General, I can hardly agree with the author when he states that the procedure to be followed is so cumbersome as to be almost useless, because as a general rule the Department has very little difficulty in obtaining from road authorities the necessary permission for the erection of lines. If similar powers could be obtained by electric supply companies, I think considerable advantage would be derived from such facilities.

Route maps.—I am afraid that the maps to which the author refers are too cumbersome to meet requirements. When it is understood that surveys have to be made in all kinds of weather, the insertion of details on the route map would be an inconvenient arrangement. In my opinion it would be better to have a stiff-backed pocket-book, say 6 in. by 4 in., each page being ruled with horizontal lines about 1 in. apart, so that as the survey proceeded particulars associated with each pole or span could be recorded in the ruled off spaces.

Safety factors.—The author is doubtful whether the Post Office figures are sufficiently conservative. The question of strength in the building of a line is, after all, a matter of cost. It would no doubt be possible to construct open lines to withstand the severest storm, but in view of the desirability of restricting the enormous expense entailed thereby, the present safety factors have been adopted by the Department. Telegraph lines may frequently be seen to be damaged in heavy snowstorms, but these breakdowns do not always occur in the same places, and, after all, the average number of times which a line is subject to breakdown is only once in 10 years.

Wood and steel poles.—The author mentions that poles creosoted by the "Rüping" process are cleaner to handle than ordinary creosoted poles. From my own personal experience I find that the amount of free creosote on the surface of timber newly treated by the Rüping process is as great as that on timber creosoted in the ordinary manner. The principal advantage claimed for Rüpingized poles is that they are adaptable for painting. The Post Office has recently erected a number of these poles at Darlington, and time will show whether the creosote will ooze through the paint. Before applying paint to Rüpingized poles they should be thoroughly planed to obtain an even surface for the priming colour, otherwise the free creosote on the surface will soon make its appearance through the paint, more especially if the latter be of a light colour. Where the amenities of a neighbourhood are to be considered this is of considerable importance. With regard to the use of steel poles, I quite agree with the author that these should be avoided. Owing to the impossibility of inspecting the insides of the tubes, their actual condition can never be definitely ascertained, and many accidents have occurred from steel poles breaking whilst men have been engaged in work upon them.

Aluminium conductors.—I am very glad to know that the use of aluminium by supply companies is being extended.

Mr. Elliott. Experiments were made some years ago by the Post Office with aluminium wire for line-conductor purposes, but the results then obtained were not sufficient to justify its adoption; the light wires were blown about to such an extent in the wind that they quickly broke off at the insulators. The success attending the use of aluminium by supply authorities may be due to the conductors being stranded, and being of such a weight that they do not blow about as would be the case with lighter wires. I notice from the table of suggested tests for hard-drawn aluminium that the author makes no reference to a "twist" test. I do not know whether this omission is intentional, but in my experience such a test is of even more importance than a wrapping test.

Telephone wires.—The arrangement whereby the line wires at every fifth pole are transposed is of course beneficial, but if the question of cost is not a material factor greater efficiency will be secured by revolving the wires a quarter of a turn in each span.

Mr. C. E. ELDER: Insulators are one of the most important parts of a high-tension line, and therefore too much attention and care cannot be exercised in connection with the packing and fixing of them. I do not advocate cement of any kind for pin-type insulators, as my experience in this direction has been very unfortunate, especially with cements which have to be liquified by heating. I am strongly in favour of hemp twine packing, as mentioned by the author, and I consider that insulators should never under any conditions be fixed by unskilled persons. A few points have to be considered in order to pack an insulator successfully with hemp twine. The pin must be made the correct size, with due allowance for the packing, and with a rough cut thread to grip it. The hemp twine must be the correct size so that only one layer is required, and also the packing should not be too tightly spun, so that it beds itself into the threads of the insulator. It is also important to insert a felt wad at the bottom of the insulator hole. There is also a method of tying the ends of the packing which I will not mention in detail. I may say that insulators packed in this manner will stand the full terminal stress of a line without moving in the slightest, and I have seen them in use on conductors of 0.15 sq. in. section. The only difficulty which I have experienced in connection with the twine packing system is that the holes in the insulators vary a little, and of course with a standard size of twine this may make the insulator either too slack or too tight. It is therefore important that each new delivery of insulators should be examined, and a little adjustment of the packing puts matters all right if there is a variation in the holes.

Pole-line work has many fascinations, and to be a successful constructor one must be prepared to tackle details. Underground cables are laid in the earth out of sight, and are forgotten until something happens. It is not so with a pole line, and I wish to make a claim for what I might term the artistic beauty of pole lines. There is no doubt that well-constructed lines will in the future have a considerable influence in connection with way-leaves, especially in and near residential districts, and is it surprising that this question of appearance is raised when there are such unsightly telegraph and colliery power lines? Even in our public streets we are constantly confronted with crooked tramway poles, evidently

set intentionally from 6 in. to 9 in. out of plumb. These conditions create bad impressions and are not helpful in the advance of pole-line work generally. It is gratifying to notice from some of the author's lantern slides that such points are receiving due attention. I do not for one moment say that appearance is everything. I would not even allow that it should add to the cost; it is simply a question of careful lay-out and close supervision, as the material for extra-high-tension lines must necessarily be of the best quality, and I think it is the duty of every engineer who has to deal with pole lines to keep this point in view.

Mr. H. BRIDGES: In the construction of high-tension overhead transmission lines efficiency, reliability, and continuity of supply are of first consideration. To secure these conditions it is essential, as the author has emphasized in the early part of his paper, that every detail, however small and apparently unnecessary, must be given close attention. In all classes of engineering, especially in the erection of machinery, it is very important that the greatest attention be given to every detail, or otherwise much damage and inconvenience will result. This also applies equally to the construction of overhead lines. Taking into consideration the severe weather and various other conditions to which overhead lines are subjected, the neglect of small and insignificant details, bad workmanship, and the "that will do" method are bound to lead to serious and constant breakdowns. The maintenance of overhead lines must also be taken into consideration, as good design and construction will considerably reduce the maintenance costs and also increase the life of the lines. In the past the maintaining of lead-covered pilot and telephone cables suspended with leather hangers to a catenary wire has been a very costly item and was threatening the practical use of the overhead suspension of lead-covered cables. During high winds the long leather hangers would get blown out of position, causing long sags in the cable, which resulted in the cable breaking down. Many months have been taken up in carrying out repairs and the re-spacing of hangers; and before some of the longer lines could be finished the whole of the work previously done would have to be repeated, the hangers being again displaced and the cables thus further damaged by another wind storm. One bad feature was the long hanger then in use. It is very important that the hangers should be as short as possible, so that in a high wind the catenary wire and the cable will swing together. If the hanger is long, even if clipped to the catenary wire, an uneven swinging will result, causing a flapping of the cable and eventually leading to breakdown. The use of the "Elder" hanger has solved the problem of the suspension of overhead cables, and is a combination of the necessary points required, viz. a short hanger and the prevention of displacement by winds. Since this hanger has been adopted the maintenance costs are practically nil. The arrangement also adds considerably to neatness, as can quite readily be seen by comparing the old and new method of suspension.

With the advent of the "Merz-Hunter" protective system for overhead lines the pilot cable is not required, and where telephone communication is not necessary, or can be given by some other source, the suspension of overhead lead-covered cables need not be considered. On all

ges. high-tension networks of any importance telephone communication with the source of supply and between substations is very necessary. To run bare telephone wires on the same poles as the power lines is not advisable, as the continuity of telephone communication during storms when the power lines have been damaged is very essential. This cannot be guaranteed with bare wires, as these would, no doubt, be the first to suffer; and to have power lines out of commission and under repair without telephone communication would be very serious. To secure the continuity of telephone communication it is therefore necessary to run lead-covered telephone cables suspended to catenary wires, and the "Elder" method of suspension is the only one which at present can be relied upon to give continuity.

Mr. J. R. BEARD: In connection with the slides showing an actual overhead line after a heavy snowstorm, I was impressed by the fact that while all the power wires were coated with snow to a diameter of about 5 in., the lead-covered pilot cable and its catenary wire were apparently quite free from snow. I should be glad to know whether the author can suggest any explanation of this.

Mr. W. P. WARD: I have only two points to mention. One is with regard to earthing, a point on which the author lays great stress, and I should like to describe an earth-plate which was recently shown to me. It consisted of the usual cast-iron plate about 2 ft. square, across the centre of which the copper earth-strip was sweated and bolted. The advantages of a plate of this description are: (1) better contact between the earth-strip and the plate and (2) that no joint is required between the bond ends and the earth-strip. The other point is in reference to the erection of the inverted type of trifurcating box for split conductor cable. It would be a very good idea to assemble the cables in these boxes at the bottom of the pole and make a joint afterwards. The author informs us that the life of steel poles in a Lancashire industrial town was 14 years; on this basis I should like to know what he estimates the life of the Blyth towers to be.

Mr. A. GILLOTT: The author mentions that great attention must be given to details. In this matter I entirely agree with him, but I have found that the most important item to watch is the man who is doing the work. The slide showing the accumulation of snow on the lines is of very great interest to me. It brings to my mind an instance about 4 years ago when I saw some Post Office wires of No. 14 gauge increased to 3 in. in diameter due to the accumulation of snow and ice upon them. I was in the vicinity when the poles broke due to the extra weight. In the same district a high-tension pole line with aluminium conductors did not suffer to such an extent. The accumulation of snow and ice on the wires, which were 0.6 in. in diameter, did not amount to 3 in. as in the case of the Post Office line. This is probably due to certain chemical action on aluminium conductors, to which the author refers. The question of hanging telephone cables by catenary wires, using the method described by the author, is of very great importance. On one of the pole lines which we constructed we had a considerable amount of trouble with the telephone cables breaking at the hanger supports; the breakage mostly occurred near the poles. In this instance

the poles were approximately 80 yards apart, which, with the use of aluminium conductors, necessitated a sag of approximately 8 ft. in the centre of the span. The adoption of a newer method got over this difficulty. The author mentions the cushioning effect of insulated pins. The old method of using Phelps' metal is to be deprecated; hemp or spun yarn and tallow are very much better. With regard to binding wires, this is a point which should be very closely watched by the clerk of works. I have seen cases where solid conductors were used. The workmen had actually used as a binding wire a piece of the line conductor which had a cross-section of 0.025 sq. in. With regard to the actual erection of the poles, some contractors have a weakness for using long spikes for pushing up the poles, and also for using climbing irons for mounting the poles. This gives the poles a very untidy appearance and becomes a nuisance when men have to climb the poles for inspection purposes or repairs.

Mr. GREGORY: Which in Mr. Welbourn's opinion is the safer method of supporting a three-phase line? Should the three conductors be placed side by side horizontally, or should they be placed one above the other vertically? The former method seems open to considerable danger from short-circuits, due to the swinging of the wires in a high wind. Wires swing in an arc of which the radius is equal to the amount of sag, so that conductors spaced 3 ft. apart horizontally and with a sag of 6 ft. in the centre of a span might under certain conditions touch when swinging only some 15 degrees from the perpendicular. On the other hand, conductors hung in a vertical line will never touch when swinging, but are liable to the snow-loading troubles mentioned in the paper. I should like the author to state which method, from his experience, he considers the better job.

Mr. G. L. PORTER: On page 191 the author states that where lead-sheathed telephone cables are used ordinary low-tension telephones may be employed; but he recommends the installation of spark-gaps, etc., to protect the user from shock in case a fault current in the sheath induces a pressure in the cores. Quite apart from the inability of the spark-gap, which acts after the voltage rises, to prevent a shock, I would point out that the cause which the author gives is small compared with another cause of shocks. Unlike underground cables with heavy lead sheaths, overhead lines possess only a poor return path for fault currents in the steel catenary and the lead sheath of the telephone cable. The return path through earth is also poor. A good earth-plate has a resistance of 4 ohms, which means 8 ohms for the two in series in the return path. The outgoing copper resistance of a heavy line may only be, say, 4 ohms per phase. It follows that in the case of an earth fault near a sub-station two-thirds of the pressure-drop in the circuit is between the earth-plate (including all connected to it) at the sub-station and the earth-plate at the power station. This can be—and obviously has been in certain cases—several thousand volts. If spark-gaps and heat coils are used at both ends of such a line they promptly put that telephone out of commission just when it is required. Apparently the solution is to employ spark-gaps at one end of the line only, and at the other to insulate the user from the instrument or—what is probably cheaper—from the building,

Mr. Porter. e.g. by means of a rubber mat. "Split conductor" lines—especially in the heavier sections—have an advantage to which I would draw attention, namely, the considerable reduction in reactance. Comparing some existing 3-conductor and 6-conductor lines of equal ohmic resistance (0.16 ohm per 1,000 yards) the reactance is 0.25 ohm and 0.15 ohm respectively per 1,000 yards. This makes a big difference in the pressure-drop when feeding the usual induction motor load.

Mr. C. VERKIER: I have already taken part in the discussion on this paper in London, so that I will confine myself to points with which I have not already dealt. The table on page 178 illustrates a point of interest in connection with the statement which one still hears, even in these days, that any advantages gained by centralizing generating plants are frequently nullified by the cost of the transmission system. With a current density of 100 amperes per phase—with which the overhead lines will deal comfortably, although this is quite the limit for the 20,000-volt cables—a 0.1 three-phase line will deal with 6,574 kw. On this basis, the capital cost per kilowatt transmitted per mile is 2s. 10d. for the overhead line, and 6s. 5d. for the underground cables. Thus, with an overhead line, for every pound sterling saved in capital cost by erecting a large station as compared with a small one, it is possible to transmit 1 kw. over a distance of 7 miles. Transmission losses cannot of course be entirely neglected, but become relatively insignificant owing to the greater efficiency of the larger generating units and the reduced cost of generation resulting from improved load factors and reduced labour charges. I agree with Mr. Hunter that it would perhaps be fairer to compare the cost of 11,000-volt cables against the cost of 20,000-volt overhead lines on account of our somewhat excessive thicknesses of dielectric, but even so the saving in capital cost by the use of overhead lines is still nearly 40 per cent, an amount which cannot be neglected. I see that the costs given for the overhead lines in this table have been criticized by speakers at other local sections, and in this connection I should like to say that lines have been, and are still, frequently erected by non-statutory undertakers for half these prices, or even less; but it is unnecessary to add that such lines do not comply with the Board of Trade requirements in many respects, and are of such a character that they give rise to the idea which commonly exists that overhead lines are unreliable and expensive to maintain. Many of such lines give constant trouble and frequently require reconstruction in a very few years. The figures given in the table are representative of the very best work in each case; and on the other hand I know that some of the lines illustrated by the author in his lantern slides cannot have been erected for anything like these figures.

On the question of reliability of operation, I need only say that it has been the policy of the power companies in this district for some years past never to lay an underground high-tension transmission cable if it is at all possible to erect an overhead line; and while such lines have not reached the almost absolute perfection of underground transmission cables, yet with the ring-main system it is possible to give a satisfactory and quite reliable supply. Some of the most important services to which electric power can be applied, such as pumping and

ventilating in mines, are now given on quite an extensive scale in this manner.

With regard to maintenance, I am unable to give actual figures, as it is not our practice to keep separate maintenance costs of different classes of mains, but I estimate that the maintenance cost of our high-tension lines is not more than 2-3 per cent per annum in normal years, that is, years without exceptional storms such as that of last year. In support of this statement I may say that we employ only 4 linemen and 2 patrol men, who deal with the maintenance of over 100 miles of high-tension lines, including a somewhat greater mileage of suspended lead-covered pilot and telephone cables, and also with the maintenance of 12 overhead distributing networks and a large number of short distributing lines. This result could not possibly have been achieved without the very great care which is expended on the design and workmanship on these lines in the first instance. All lines should as far as possible receive a thorough overhaul every year during the summer months, when necessary renewals can be made and the equipment kept up to a high standard. Every 5 years or so it is also good practice to renew binders, re-sag the wires, plumb poles, and generally give greater attention to the upkeep of the line. I see no reason why lines substantially constructed in the first instance and regularly maintained in this manner should not have a life of at least 30 years, or as long as the poles last. The erection of insulators suitable for ultimate use at higher pressures is in my opinion good practice up to a certain point, and we have for the past year or two given up making any difference in design for lines between 6,000 volts and 20,000 volts, all our lines being standardized for the higher pressure. The extra cost is entirely due to the insulators, and is small, but there follows the great advantage of having standardized material. At pressures above 20,000 volts, however, I think I would adopt suspension insulators, as the present insulators we are using for a pressure of 20,000 volts are about as large as can conveniently be handled. We have found it desirable to use much larger insulators than are employed for similar pressures abroad.

The author hopes the Board of Trade will sanction overhead lines along public roads. This is a question which we have often discussed, but I take the view that generally speaking a public road is not a suitable place for high-tension overhead lines. Our roads in this country are too narrow and tortuous, and often with insufficient room at the side for the satisfactory erection of a heavy line, while it is unusual to find a road without some Post Office wires on one side, and as the Post Office require a horizontal clearance equal to at least $\frac{1}{2}$ times the height of the conductors, it is seldom that this clearance can be obtained. Notwithstanding all this, I believe the Board of Trade is even now prepared to grant consents for such lines where the conditions are favourable, and where a suitable protective gear is employed. The remarks which I made in the discussion in London on the advantage of "short cuts" should, however, be borne in mind; while if a line is erected satisfactorily along a public road in the first instance, trouble is sure to arise where dwelling-houses are subsequently erected on the frontage of the adjoining land. Mr. Elliott said he thought the Postmaster-General's powers were sufficient and satisfactory. I am afraid he is

not clear that the statement applies only to powers for carrying overhead wires across private land. As I was responsible for the statement originally, I would add that I refer to Section 2 of the Telegraph Act, 1862, and Section 4 of the Telegraph Act, 1908, which deal with the question. I believe there is not a single case on record where the Postmaster-General has exercised his powers under these sections.

On the question of protection against lightning, it may be remarked that in this, as in many other respects, the meteorological conditions in this country are generally favourable to overhead lines when compared with other countries where overhead lines are chiefly used. Severe lightning storms, as is the case with severe snowstorms, are of infrequent occurrence except in certain localities. I do not know what peculiarity there may be in the system conditions on the North-East Coast, but it is somewhat remarkable that all the usual protective devices which are so carefully installed on much smaller undertakings have either never been used at all or have been abandoned. I refer to mains charging gear, roller spark-gaps, and lightning arresters, resulting in a very considerable saving of capital and maintenance cost. Notwithstanding the abandonment of lightning arresters on our overhead lines, our troubles from lightning are certainly no worse than before, and very infrequent. One unusual experience which may be recorded occurred last summer on a line under construction, where a 2-mile section which was not connected up or earthed in any way was affected by a lightning discharge and to insulators were punctured.

The suspension of lead-covered cables is a matter to which we have given very great attention, resulting in the method of suspension patented by Mr. Elder. Some extremely rapid failures of many miles of suspended lead-covered cables from crystallization of the lead sheath caused this matter to be fully investigated. There are several points of the greatest importance in connection with this work,

and I would add that it is impossible to say that any one of them is of any greater importance than another. These points are as follows: (1) Some hardening material should be put into the lead sheath. (2) All hangers must be of equal length so that each shares the weight of the cable. (3) Such hangers must be as short as possible so as to prevent the formation of ripples which otherwise run along the lead-covered cables, and to compel the lead cable and catenary suspension wire to swing together. (4) Hangers should be spaced preferably 12 in. apart, and not more than 18 in. (5) The hangers should be secured to the catenary wire or lead sheath so as to maintain the regular spacing and prevent creeping of the lead-covered cable. It will be seen that all these features are incorporated in the Elder hanger, and that none of the usual methods of suspension pay proper attention to these essential points. Much damage of suspended lead-covered cables results from the hangers acting as sails and dragging the lead-covered cable along with them when a wind blows in the direction of the line, and especially from the hangers being either too long or too widely spaced. The author states that only high-tension telephone instruments are permissible with bare telephone wires. I thoroughly agree, but I should like to know what percentage of such cases one could find where these instruments are used. Bare telephone wires should certainly never be allowed without them, but here again non-statutory undertakers are allowed to do as they please and use bare wires without them. In conclusion, I should like to ask the author whether he has any experience to show that long spans are safer than short ones under ice loading. In the storm last year it was noticed that the only breakages of conductors which occurred, apart from fusing, were at guard spans, which are usually very short.

The author's reply to this discussion will be found on page 317.

MANCHESTER LOCAL SECTION, 13TH JANUARY, 1914.

Mr. C. D. TAITE: The author has dealt with a subject which is undoubtedly of growing importance at the present time because overhead lines are developing very rapidly, and those of us who are interested in their erection know very little about what is being done in other districts. If the author's suggestion of a Transmission Lines Committee could be adopted, I think it would be fruitful of very good results by standardizing practice and bringing to the notice of those interested what is being done in other places. On page 178 the author gives a table comparing the cost of underground cables and overhead lines of similar capacity. I do not agree with that table at all. My experience is that the cost of underground work is more nearly 3 times the cost of overhead lines of the best quality. The company with which I am connected usually install duplicate lines or duplicate cables as the case may be, and I have some figures of the actual cost of installing a 0.1 sq. in. underground cable and an 0.1 sq. in. overhead line. The underground cable, in duplicate, cost approximately £2,600, and the actual cost of an overhead line of similar capacity, in duplicate, was £953, which is practically what the author has given for a single line. We

always assume that the cost of an overhead line is approximately one-third that of an underground cable, a duplicate transmission being taken in both cases.

I know there is a growing tendency to use aluminium conductors, but I think there are still many serious objections to their adoption for overhead lines. In the first place the sag is very much greater; that involves either more poles—and the difficulty of getting wayleaves is very great at present—or higher poles. In the second place it means wider spacing of the conductors, because the swing will be greater; this again means stronger cross-arms. There is also a third trouble, namely, the connection of the aluminium conductors to the underground cables. This is a rather serious problem, and so long as copper is used throughout it is one with which no trouble whatever is experienced.

With regard to cross-arms, my company have adopted, and still use in every case, oak cross-arms. Owing to an accident a high-tension 10,000-volt conductor lay on such a cross-arm for 3 days, and in the course of that time burnt a hole in it. If we had not used oak cross-arms the supply on that route would have been interrupted. In connection with

Mr. Tate.

the tying-in of conductors, we have again adopted what Mr. Weibourn objects to, namely, rigid clamps. The type which we have adopted is very simple in construction and has never given a moment's trouble. We claim that it can be erected in all weathers, whereas I think some of the types of binders which the author has described in his paper must require either good weather or particularly skilful men for them to be erected with absolute safety. We have not experienced the trouble which the author refers to in connection with mechanical clamps, namely, friction interfering with the glaze on the porcelain; but the makers of the insulators state that they do not depend on the glaze for insulation. As a matter of fact in some districts where we have had trouble from broken insulators these have lasted for weeks, although it appeared from the ground as if they were almost completely shattered. Neither have we had any trouble from crystallization: our experience extends over a period of 8 years.

We have had one or two cases in which a line has been struck. One occurred last year, and the result was that two miles away from where the lightning flash was thought to have occurred an oil switch broke down. In another case a transformer broke down. We have various forms of lightning arresters, chiefly of the static discharge type, consisting of a number of gaps and carbon resistances. We also have an aluminium arrester at the station, but apparently the storms take place so far away from the station that the aluminium arrester does not seem always to deal with them. American engineers always tell us that the aluminium arrester is the best; but it is by far the most expensive. As pointed out by the author, a great objection to the use of aluminium arresters is that they require daily attention. This renders them quite unsuitable as at present constructed for ordinary static sub-station work. On page 180 reference is made to a practice adopted by Messrs. Merz & McLellan in connecting up their lines at both ends by paper-insulated cables. This is a point I am not quite able to follow, as I think the connections are usually made by bare copper wires. In regard to the terminal boxes shown on page 192, one objection it seems to me is that there might be some difficulty in bringing the conductor either to or from the overhead line. With the ordinary form of dividing box the conductor is carried vertically from the line into the box, but with the boxes shown apparently it is necessary to make a big bend to clear the metal-work of the box, and this brings the conductor so far from the pole that there is very little hope of getting any support for it.

Mr. Watson.

Mr. S. J. WATSON: Overhead lines are at the present time one of the most important questions requiring the consideration of those engaged in the electricity supply industry. The reason is quite plain, as has been shown by the figures which the author gives as to the relative costs of overhead lines and underground cables; and here let me say that I disagree with Mr. Tate's figures and support those given in the paper. During the last year or two I have erected a few miles of 6,600-volt lines, and the actual cost of these (which consist of a complete three-phase duplicate line) and of two three-core cables in wood troughing, comes to about £1,250 and £2,450 per mile respectively. This is for conductors of 0.15 sq. in. section. The only serious difficulty which acts against the use of overhead lines is the question of wayleaves. It is one

Mr. Watson.

which is exceedingly difficult to handle, and unless it has actually been experienced, I think the difficulties which are encountered would hardly be realized. I have a particular case in mind where we wished to go across a field for a distance of about 200 yards, but on account of the objection of the landowner we were compelled to make a considerable detour which added about £1,200 to the cost of the line. We could have got across the field by erecting about 4 poles and paying the cost of the wayleave. This sort of thing cannot be to the advantage of the industry with which we are connected, and it undoubtedly has tended to restrict the supply to consumers. We must get an Act passed which will make it compulsory for landowners to give wayleaves, as is I think the case on the Continent, and if the Institution can do anything to bring about such a result a lot of good will have been done to further the progress of the industry. The line which we have erected does not differ greatly from the lines which the author has illustrated. It consists of duplicate three-phase conductors with each set arranged in triangular formation on both sides of the poles; 2 ft. 6 in. spacing is adopted, and the poles are of the A type with wood cross-arms. I have been very interested in the various forms of construction which have been shown on the screen. In this connection let me say that in my opinion the best formation is that with only three conductors on one pole; but here the wayleave question comes in again. It is necessary to have a duplicate line, and if two sets each of three lines have to be erected it means a duplicate set of wayleaves and thus a further check.

One of the most important points in connection with overhead lines is that of guarding. The Board of Trade have to call for this protection in the interests of the public, but it often adds appreciably to the cost of construction. It will have been seen what a very heavy and ugly appearance it gives, particularly when the cradle form of guard is adopted. There have been a number of improvements since then. The type we have in use is a split conductor on road crossings, with clips at intervals across the span, so that if the line breaks it is still well out of reach of any animals or people passing along the road. It has quite a neat appearance, far preferable to some of the other arrangements shown, and it is also easily and quickly erected. I have been trying to imagine the feelings of an ordinary landowner who granted a wayleave for the pole shown in Fig. 17 when he saw the complete structure. Such an erection would not be tolerated in many parts of the country. The earthing arrangements have also been referred to by the author. If it is necessary to use an earth-wire—and the Board of Trade are now insisting on this—the proper material to use is copper or bronze. It will last much longer than steel and will give much more satisfaction. I think also that the proper place for the earth-wire is at the top of the pole, because in this position it will provide some protection from atmospheric disturbances. I should like the author to give further information in regard to the troubles experienced from lightning on some of the lines in Wales. Some exceedingly useful experience must have been gained on those lines, as they extend for considerable distances on high land in an area where atmospheric disturbances frequently occur. The triangular guard shown in Fig. 16 appears to

be an exceedingly simple and good arrangement, particularly where it is used on a three-line transmission. It could no doubt be used on a six-line transmission, but it is better for only three lines. The question of aluminium conductors has already been mentioned, and I am inclined to think that one of the points which requires consideration in connection with the use of aluminium or copper is their relative values as scrap materials. There is no question what the value of the scrap copper will be, but there is some doubt about the value of scrap aluminium. If the author would deal further with this point, I think it would be interesting to us.

Mr. J. LUSTGARTEN: We have had quite a number of papers dealing with foreign high-tension transmission work, but in no paper have we been informed that in England we possess 115 miles of high-tension transmission lines at 20,000 volts. And yet, when we consider foreign practice, this is not very much to congratulate ourselves upon. The present paper is very opportune, because the day is not far distant when pressures and capacities in this country will compare more favourably with those of continental and colonial schemes. The author mentions a projected scheme for 40 miles; it would be very much better if the pressure of transmission were about 1 kilovolt per mile. There are a few points in the paper upon which I should like to comment. In the first place, there is the question of the maximum wind pressure. The figure named by the Board of Trade is 25 lb. per sq. ft. of exposed effective area; but to my mind this is too great, especially as the factor of safety is taken as high as 10 for wood poles and 5 for conductors. The wind pressure for a velocity of 100 miles per hour would only be about 15 lb. per sq. ft., and for a velocity of 65 miles per hour 6 lb. per sq. ft. This last figure would be amply representative of the maximum wind velocity in this country; but to be on the safe side 10 lb. might be taken. The effect of sleet or ice has been left out in Appendix II. I do not think this is altogether wise, as it would affect not only the sag formula, but also the angles given in Appendix XI. Allowance might be made for a coating of sleet or ice about $\frac{1}{2}$ in. thick. The author gives a formula for finding the dip between two towers on the level. The following formula might be added for the dip with the towers on different levels—

$$d_s = d (1 - h/d)^2,$$

where d_s is the maximum dip of the wire, h the difference in height of the points of support, and d the dip when the points of support are on the same level, and for the same tension. This formula assumes no wind. If $h > d$ the wire slopes continuously upwards. A resultant force on an insulator should never be allowed to be upwards. Referring now to the author's data for spacing; it might be of interest to give here an empiric formula which agrees very well with practice—

$$s = (1 + 0.1 \text{ kv.}) \text{ feet,}$$

where s is the spacing. In the Victoria Falls and Transvaal Power Company's 80-kilovolt line the spacing is 9 ft. With reference to the formulae for self-induction and capacity, it is perhaps well to point out that the logarithms

given are common logarithms and not Napierian. Might I also mention that the formula for capacity of the conductors arranged in one plane is only approximate? It is unfortunate that the author has drawn the vectors in Fig. 3 in the reverse direction to that now agreed upon.

I cannot agree with the author's statement that certain insulators failed because their glaze was cracked. The glaze on porcelain is often of uneven thickness, and is not always perfectly continuous; and unglazed insulators of the highest grade porcelain have as high an electric strength as those that are glazed. The requirements for insulators are that the porcelain should be vitrified throughout; so that there is very little to gain, at the best, from the slight additional thickness of the glazing. Unglazed porcelain attracts moisture and dirt, and on account of the irregularities of the surface would be difficult to clean. For this and no other reason (excepting, perhaps, the use of coloured glazes) a coating of smooth and durable glaze is employed. With reference to Messrs. Buller's specification in Appendix XII, it were best that the "test voltage dry" in the routine tests should be amplified. The reason that this is 20 per cent less than the "flash-over voltage dry" is that the insulator is inverted in a pan of water which reaches to the neck, so giving a smaller flash-over distance. Lines which are exposed to lightning storms and those which are discarding the horn-gap arrester in any of its forms require of their insulators a high safety factor against puncture. These may withstand high electric pressure of low frequency, viz. the "flash-over dry" voltage (Appendix XII), but may not withstand a high-frequency surge giving a pressure rise at the insulator of the same flash-over value. A definite time-interval elapses for sparking over (ionization of the air) to be established, and meanwhile the pressure rise may have reached the puncture value. A high-frequency test would be of some value in determining the ability of the insulator to withstand such shocks. It would appear that insulators with wide and thin shells do not withstand lightning shocks, so that for line pressures up to 40 or 50 kilovolts pin insulators with thick walls between pin and line wire would more easily meet the case. A composite pin, made of wood in the part which screws into the head of the insulator, would relieve the stress, causing breakdown to take place rather through the air path than through the porcelain. In Fig. 6 a special type of suspension insulator—fish-tail interlink pattern—is shown, used for straining purposes, the suspension insulators being also used for leading into stations. In the case of the Ohio Brass Company's type (used also in the Tata Hydro-Electric Power Company's scheme) there is no difference between the pattern used for suspension and that for straining purposes, except that for straining purposes a higher mechanical strength is needed. In practice, one or two more insulators are used for straining than for suspension purposes; e.g. on the transmission line of the Hydro-Electric Power Commission of Ontario 8 are used for suspension and 10 for strain. I have found that there is but little difference in the wet flash-over voltage for these insulators in either the suspension or strain position; as a matter of fact in the former case the drops of water from the topmost insulators assist the

* H. W. BUCK. "The Use of Aluminium as a Conductor." *Transactions of the International Electrical Congress*, St. Louis, 1904.

Mr. Lastgarten

flashing-over, whereas the drops of water fall clear of the insulators when in the horizontal straining position. Photographs of spark discharges preceding flashing-over verify this statement.

I wish to endorse the view taken by the author as to horn arresters. The discharges across these are very liable to produce oscillations, which passing to the line may cause arcing over at an insulator, or maintain arcing at an insulator if it originally caused the arrester to act. Oscillations may also be produced on the transformer side. The ohmic resistance of the line is depended upon to damp out the oscillations, but in some stations in Switzerland and Italy which I visited last year I noticed that batteries of Mosciicki condensers were used to absorb high-frequency surges. The slides show those in use at Beznau station on the Beznau-Lötsch transmission line at 25 and 40 kilovolts, the horn arrester having been discarded. Additional choke coils were required. A condenser has the advantage that for the same terminal pressure it will allow a greater current to pass the higher is the frequency of the oscillation. In Continental hydro-electric plants charges insufficient to cause arcing are prevented from accumulating or wandering on the line by the use of water-dropping devices which give the charges a free path to earth.

Mr. Hollingsworth.

MR. E. M. HOLLINGSWORTH: I quite agree with the author that in industrial districts it is advisable to use poles of wood, provided, of course, that every care is given to their selection and treatment. In connection with one of our pole lines, on account of increasing the number of conductors we had a short time ago to replace several poles which were planted 12 years ago. We found all these wood poles to be in as good a condition as on the day when they were put in. As pointed out by Mr. Taite, poles and cross-arms of wood also give the advantage of a greater insulation resistance. We have had a similar experience of the burning of a cross-arm by a conductor without interfering in any way with the supply. As to corner poles, it is my experience that properly constructed A-poles are more reliable than H-poles; in fact I have found it necessary in several instances to replace H-poles with A-poles. With reference to line conductors, we have had short lengths of aluminium conductors under observation for the last 5 years, with the result that I have recently erected a considerable length of bare, stranded aluminium cable, consisting of 37 strands of 0.152 in. diameter, equal to a sectional area of 0.66 sq. in. We have used mechanical clips for the last 12 years, and they have proved quite satisfactory. I consider the triangular guard, as illustrated on page 191, will find favour with many engineers, especially for low-tension work. We have adopted this system of guarding in connection with a line supplying a 400-volt three-phase four-wire distribution; and in order to comply with the Board of Trade Regulation as to earthing at one point only, each triangular guard is connected to the fourth or neutral wire, but is insulated from each pole.

Mr. Medlyn.

MR. W. J. MEDLYN: I agree with the author that the wayleave powers possessed by the Postmaster-General could be extended with advantage, having regard to the insistent public demands for the extension of the telephone and telegraph systems, and especially in those cases where new services are required at short notice. Personally I

am glad to be able to disagree with the statement that the powers conferred under the various Telegraph Acts are "almost useless." Some road authorities are not so helpful in the matter of wayleaves as they might be; but others recognize the public convenience represented by the telephone and telegraph services, and co-operate with the Department by conferring ready facilities for the extension of the system. The value of the Telegraph Acts depends to a considerable extent on the measure of assistance and co-operation which the Post Office receives from the highway authorities. The author appears to press for additional powers for an increase in the number of overhead high-tension transmission lines in urban districts; but the reason for this is not quite clear. The table given on page 178 shows the difference in cost between underground and overhead construction, but presumably the overhead figures apply generally to a rural district. In an urban district, owing to the presence of buildings and other obstructions, the cost of construction would be considerably increased, while owing to the presence of numerous telegraph, telephone, and tramway trolley wires, the guarding arrangements and protective devices would probably be complicated and costly. The author points out that annual charges in respect of overhead lines are greater proportionately than for underground cables, and there seems little doubt that this difference in favour of underground work would be accentuated in thickly populated areas. A statement showing the comparative annual charges on overhead and underground systems respectively would have been interesting. At one time the erection of overhead power wires in cities in the United States and Canada appears to have been greatly overdone, as a consequence of which numerous fires and fatal accidents resulted. In 1907 the American Bureau of the National Board of Underwriters furnished information to the effect that in the United States between 10th January and 10th April of that year—a period of just over three months—21 fires were caused by high-tension lines falling on telephone and electric light wires. About the same time public attention was directed to a number of disastrous fires caused by the general use of overhead power wires in Montreal City, as a result of which it was recommended that the wires should be placed underground. In June, 1908, an American journal called attention to the serious results of intermingling high-voltage electric light and power wires with telephone wires "in most cities and towns," as a result of which telephone linemen and repair men were frequently killed or injured by coming in contact with the high-tension circuits. The Board of Trade is hardly likely to agree to the copying of American practice in this respect, and of course I do not think the author had such an object in view in his brief remarks about the extension of powers within urban districts.

Factors of safety (page 179).—The author appears to assume that in the Post Office a factor of safety of 8 for poles and 4 for wires is observed in all circumstances. As a matter of fact the factor of safety is increased in exposed localities, whilst in sheltered positions the figures may be somewhat reduced. In some places the Post Office lines are liable to damage from sleet storms. No matter what the diameter of the wire may be, the gradually freezing sleet sometimes attains a diameter of 2 or 3 in. The

Mr. Medlyn

added weight (sometimes combined with wind effects) generally results in the wires breaking, and frequently the poles. In the *Post Office Electrical Engineers' Journal* of April, 1910,^{*} particulars are given of a breakdown caused by a sleet storm in the north-eastern district, which show that pieces of ice taken from copper wires weighing 100 lb. per mile were found to measure over 2 in. in diameter and weighed 12 oz. per foot. This would give a weight of about 1½ cwt. in a 66-yard span, or 3 tons in a span of 45 wires. So far as the Post Office is concerned, having regard to the frequency and extent of breakdowns of this character, it would not be economical to adopt a factor of safety that would prevent their occurrence. In the case of power transmission lines, the difficulties arising from snowstorms are probably not so great as in the case of the Post Office lines, owing to the smaller number of wires carried and the greater diameter of the conductors. I do not think the accumulations of frozen sleet are as a rule much greater on a thick wire than on a thin one. Where the safety factor is provided for by means of metal stays subject to corrosion, due account should of course be taken of the atmospheric conditions. In many places in Lancashire galvanized iron or steel wire has a very short life, and frequent renewals are necessary to maintain the original strength of materials. In some places bronze and copper wires also become weakened by corrosion in a comparatively short time. The corrosive effects are as a rule more troublesome in urban districts than in the open country.

Telephone and pilot circuits (page 189).—Perhaps it may not be out of place to issue a warning note on the subject of telephone transmission. The standard of transmission aimed at by the Post Office for communication between any two subscribers is such as would be obtained in speaking over a distance of 2½ miles through copper conductors weighing 20 lb. per mile, insulated with paper strip in lead-covered cables. With selected telephones and expert users in quiet surroundings, conversation could be maintained on such a circuit rather more than 40 miles in length. If the conductors are covered by a solid insulator such as gutta-percha or indiarubber, the transmission distance is very considerably reduced as compared with paper insulation, which provides an air space round the conductors. The author suggests that solid insulation might be used up to a distance of 40 miles; but under such conditions speech is not likely to be satisfactory, especially if conversation has to be carried on in close proximity to noisy machinery. A case bearing on this point came under my notice some few years ago where an important power company laid down an extensive underground transmission scheme between a number of towns. Telephone conductors were included in the same cable with a view to providing a complete system of telephonic inter-communication between all the stations for the purpose of controlling the power equipment; but unfortunately on completion of the work the use of the telephone conductors in the manner intended was found quite impracticable owing to the low grade of transmission.

Transposition of telephone wires.—The termination of two wires on a single insulator, as shown in Fig. 14, is open to the objection that dirt and spiders' webs are liable to cause

partial contacts, while even with comparatively clean Mr. Medlyn
insulators the surface leakage in wet weather would be considerable, tending to interfere with the ringing as well as with the speaking efficiency of the circuit. In the Post Office it is the practice to terminate wires on separate insulators where transposition is necessary. The transposition method of running telephone wires is satisfactory where only one or two pairs are concerned; but where the lines are numerous the transposition arrangements which are necessary to prevent cross-talk between the pairs become very complicated. The rotary method referred to by the author is used in the Post Office.

Guarding of conductors (page 191).—The important question of guarding and protective devices offers a wide field for discussion, upon which I do not propose to enter. For those who are specially interested in this matter from the Post Office point of view, I cannot do better than recommend the perusal of a paper read by Mr. Bartholomew before the Metropolitan Centre of the Institution of Post Office Engineers in December, 1908. This paper deals with the subject very comprehensively, although in some respects it may not now be quite up to date. Copies of the paper are obtainable from the Librarian in the Engineer-in-Chief's office.

Mr. J. D. PATON: Several speakers have emphasized the necessity of considering the economics of the case. It is well known that an aluminium line will transmit the same amount of power over the same distance and with the same number of watts loss as will a copper line of double the weight. Taking copper at £60 and aluminium at £85 per ton, it therefore means that two tons of copper at £60 are equivalent to one ton of aluminium at £85. Other speakers have mentioned the additional cost due to larger poles having to be used. The actual facts prove that on an average the cost of the poles for an aluminium line is 15 per cent higher than that of the poles which would be required for a copper line. This extra cost of the poles, however, is more than offset by the saving in the cost of the wire. The economy of aluminium is therefore established. Also, in view of its higher efficiency and the increased economy, I do not think even the most aesthetic engineer would raise a very serious objection to the greater sag of an aluminium line except when a copper line is in close proximity to it. As to scrap values, it may be of interest to members to know that in this neighbourhood aluminium has been purchased at a certain price and subsequently sold at a higher price. In modern lines stranded conductors are used for aerial transmission, and I might point out that although an aluminium transmission line might have to be taken down, the same strands are equally available for reconstruction into ordinary industrial cables. Modern developments have so established the purity of aluminium that corrosive effects can be practically disregarded. Looking into the future with regard to the possible developments of electrical engineering, the universal application of electrical power can only be effected by economy and efficient methods of distribution; and the final solution of this problem and the key of the position will be found in aluminium.

(Communicated): In his reply at the meeting Mr. Welbourn mentioned a case where copper had been bought for a certain price and resold with advantage to the customer after many years' use. He stated that the differ-

* T. B. JOHNSON. "A Record Breakdown." *Post Office Electrical Engineers' Journal*, vol. 3, p. 25, 1910-11.

Mr. Paton. ence between the value of the ordinary ingot and that of the scrap material was £6 per ton for copper and £20 per ton for aluminium. This would give the primary impression that there was a difference of £14 in favour of copper; but we must remember that in any scheme where aluminium is employed, only half the weight of metal would be necessary compared with a copper line under the same operating conditions. It must therefore be realized that the above £20 must be divided by 2 in order to give a true comparison, and the difference would become £4 instead of £14 if the aluminium had to be realized in the scrap market. As a matter of fact the loss likely to be incurred should a sale at scrap prices be necessary will almost be recouped not only by this decrement in the original price but also by the saving in the annual interest due to the lower first cost of aluminium lines.

Mr. A. F. W. RICHARDS: With regard to the table on page 178, it is of course true, as the author says, that the working pressure has little influence on the first cost of an overhead line, mechanical problems being far the more costly to overcome. At the same time I scarcely understand how the author makes out the cost of an 11,000-volt line as being equal to that of a 20,000-volt line. On page 185, he recommends a 3 ft. spacing for 20,000-volt and 2 ft. 6 in. for 11,000-volt lines, and in the specification given in Appendix XII he suggests a considerably severer test for the insulators. Surely these considerations must increase the cost of the line, even though it may be only to a trifling extent. The author no doubt intends that his comparison of the cost of underground cables and overhead lines should only be very approximate, but I think he should have made this clearer. The remarks of Mr. Taite and of Mr. Watson show how the cost may vary in practically the same neighbourhood. I have known of cases where owing to exceptional circumstances an overhead line would have been practically as expensive as an underground cable; for example, where the line would have to be erected alongside a public footpath and would therefore have to be guarded throughout its length, whilst the cable could be laid in the cheapest manner possible as the excavation and reinstatement were of the simplest description. I agree with the author that the possibility of using aluminium should not be passed over without careful consideration when the cost is comparable with that of a copper line, after of course taking into consideration the increased sag and therefore spacing, which would necessitate longer poles and cross-arms. I think it has been clearly demonstrated that such a favourable comparison in cost cannot be made on lines of less than 0·1 sq. in. sectional area (copper). Such a size of line for high-pressure working is a large one, and therefore I am of the opinion that aluminium will not come for the present into general use for long high-tension transmission lines. The author recommends what I consider to be the only satisfactory method of jointing aluminium, i.e. butt-welding; in my opinion it is the difficulty of satisfactorily jointing in any other way within a reasonably small compass which has prevented the extended use of insulated aluminium cables.

Line clips.—I cannot agree with the author's statement (3) at the top of page 187. Since seeing an advance copy of this paper I have had an opportunity of examining a

large number of clips erected nearly two years ago on a 0·15 sq. in. stranded copper line. Several hundred rigid-type clips are used on this line, and a careful examination was made of 72 of these; in no single instance was there the slightest perceptible sign of the glazing being chipped or chafed by the copper stirrup clip. A minute inspection was made through a magnifying glass for crystallization of the metal of the clamps or conductors, but there was no trace of this. I may say that these clips were delivered in bulk and no trouble was taken to fit to individual insulators. For such heavy lines as this I consider that the rigid clamp is the best method of tying up the conductors. The "Elder" suspender is certainly a good way of getting over the trouble of longitudinal movement of slings supporting insulated cables, but I do not quite like the retention of the old eyelet, which sooner or later pulls through the leather thong. The type which I prefer is of the hook and wedge pattern, with a far broader seating for the cable itself; this broad seating, which consists of a lead former braided with served jute, prevents the cable from slipping through, whilst allowing the hook to slide along the suspension wire. This is of great service in erection since cable can be hauled into position by men stationed at one pole whilst the suspenders are placed on the cable and suspension wire by a man at the next pole. There is no need to pay out the cable first and then to lift it into position and adjust the suspenders in the somewhat hazardous manner depicted on one of the slides which Mr. Welbourn has shown.

Guarding.—This is one of the most difficult problems in overhead line work. On circuits where some protective device such as the Merz-Hunter is installed, I think that the Board of Trade might allow lines to be left unguarded along country roads. For small lines the guard illustrated on page 191 appears very simple and effective. I should certainly like to adopt it on small low-tension lines if Mr. Trotter has put forward the design for anybody to use without licence.

The only other point that I should like to mention is in connection with the useful tables which are published at the end of the paper. I think the author should give the formula and an example for use with the table in Appendix IV. Its use is quite clear when properly explained, but he has left too much for us to think out for ourselves. In Appendix III I venture to criticize the advisability of giving the ohmic resistance of two wires; that is, the columns are headed "Per Mile of Line" and "Per 1,000 Yards of Line," whereas they mean (it is certainly explained in Note (a), but there is no corresponding reference letter on the table itself) "Per 2 Miles of Wire" and "Per 2,000 Yards of Wire." Now nearly all lines consist of at least three wires, so the expression "Per Mile of Line" has no real significance except for a single-phase line. A multiplier of 2 in the formula would overcome this and prevent mistakes.

Mr. G. W. MALCOLM (communicated): As we are operating one of the latest examples of high-tension overhead transmission lines, the paper is especially interesting. It may be of interest to mention that this line of the Mersey Power Company has been in operation for just over 18 months, transmitting alternating current at a pressure of 6,000 volts over a distance of 8 miles, and we have had no trouble whatever, in spite of some very severe storms. Although we did not have any trouble with

local authorities or others with regard to wayleaves, we quite agree with the author's suggestions that some curtailment of their power is advisable.

Mr. B. WELBOURN (*in reply*): This discussion has proved very interesting because of the number of really useful points which have been brought forward. Some of them have been dealt with at other local section meetings, and to avoid repetition it is necessary to ask members to be good enough to read the replies made elsewhere.

Aluminium conductors have received much attention, but I fear that despite my partiality for the metal, I cannot altogether follow Mr. Paton in his enthusiastic advocacy of them. To my mind the question of using aluminium or copper can only be decided after weighing the advantages and disadvantages in each particular case and after most carefully comparing the over-all costs of each. There is no real difficulty in connecting copper to aluminium, but the joint must be protected from air and moisture unless it is in a dry place. In reply to Mr. Watson, the scrap values of clean electrolytic copper and aluminium are approximately £6 and £20 per ton respectively below the current market prices of wire bars. I am afraid that Mr. Paton has been misinformed as to the possibility of using discarded aluminium strands from an aerial line for insulated cable-making. Because of the surface scale such strands would have to be melted down into bars and redrawn into clean wire in most cases. Apart from this, it is usual, for well-known reasons, to employ a larger number of wires in an insulated cable than in an overhead conductor. Aluminium will have a better chance when the production of the metal increases and there is more of it available for electrical (as apart from mechanical) work. The price will then perhaps be lowered. Copper lines of 0.10 sq. in. and under are at present usually cheaper than the equivalent aluminium lines.

In regard to line protection against lightning and other disturbances, I think it is correct to say that the North Wales Power Company's lines have been very free from trouble since the adoption of the Moscicki condenser. Last year I examined an overhead line in the Balkans which had been much troubled with lightning. This was cured by the installation of these condensers and aircored choking coils of iron. The use of paper-insulated lead-sheathed cables for connecting up overhead lines at both ends has much the same effect as the Moscicki condenser in dealing with high-frequency oscillations. There is no real difficulty in connecting up an overhead line in this way, and I think I have seen it done on Mr. Taite's own lines. The chief difficulty has been with the terminal boxes between the cable and the line. Boxes using vertical insulators on the top arc being superseded with very satisfactory results by boxes of the inverted type. In these boxes the insulated cable can easily be sealed in with waterproof compound and the leading-in insulators can be arranged for renewal from outside in the event of breakage.

I am glad to see that Mr. Watson agrees with me about the material to be used for the longitudinal earth-wire. Its position on a line must be determined by the conditions to be met. When used below the power wires it provides a ready means of supporting a telephone or pilot cable.

One useful point that has been brought out in these discussions is the liability to trouble on lines erected in the

neighbourhood of high-powered wireless-telegraph stations, and that immunity from trouble can only be secured by keeping a line at least a mile from such a station and at right angles to the station antennae. Underground cables should be used at any less distance than this.

Mr. Hollingsworth has raised a point, which has not been discussed in the paper, in regard to transplanting creosoted wood poles. I think there is considerable evidence to show that creosoted poles have a life of fully 35 years if planted soon after creosoting and if left undisturbed. Removed poles are often found apparently as good as new, but they sometimes rot within two or three years if used again. The reason appears to be that there is no free creosote to form a fresh germicide area around the pole below the ground. I do not know whether anybody has tried pouring creosote into the holes around transplanted poles, but it would seem to be worth a trial.

The triangular guard is being developed in a variety of forms for both high-tension and low-tension work, and further information about it is given in a paper which its designer—Mr. A. P. Trotter—read before the Institution of Post Office Electrical Engineers in London on 20th January, 1914. I may say that anybody is free to use the design. Mr. Trotter's paper only deals with low and medium-pressure work, but it, and the discussion on it, contain a large amount of exceedingly useful information and make much clearer the attitude of the General Post Office and the Board of Trade on the question of guarding.

It seems to me to be questionable practice to rely on wood arms as secondary insulation. I know that it is a controversial point whether wood or metal arms should be used, and some engineers seem to put the question into the same category as "Earthed v. Unearthed Neutrals" and "Lead-sheathed v. Bitumen-sheathed Cables." Surely it is best, when a fault comes, to have to deal with it promptly and to be done with it!

Mr. Lustgarten has mentioned several useful points and supports my views on horn arresters, as several speakers have done elsewhere. I am surprised to learn that there is at the present time any doubt as to the relation between wind velocity and pressure. The *Encyclopædia Britannica* gives the following table, which is, I think, the one commonly accepted and worked to:—

	Velocity in miles per hour	Pressure in lb. per sq. foot
Calm	0	0
Light breeze	14	1
Strong "	42	9
Strong gale	70	25
Hurricane	84	36

I think it is necessary to distinguish between gusts of wind and steady pressure. Experience shows that the above pressures are not maintained all along a line, or else lines might be wrecked frequently without any snow accumulations. Trouble from wind usually comes on short spans on which the wind pressure has concentrated, and not on long spans. On lines crossing ravines and country where wind concentration may be expected, it is advisable not to erect any conductor of less than 0.10 sq. in. section. Mr. Lustgarten's suggestion about testing insulators with high-frequency pressures as well as with normal-frequency pressures is one which will, I hope,

Mr. Weibourn.

receive attention from the insulator makers and from consulting engineers. The same subject has been raised by Mr. Burnand in the Yorkshire Local Section discussion.*

I am sorry that I have already dealt with so many of Mr. Medlyn's points elsewhere, but I may explain again that my remarks on wayleaves refer to private wayleaves for "work across country." The information in regard to corrosion is very valuable, backed as it is by so much Post Office experience. It confirms the remark which I made while reading the paper, that in urban districts it would be an improvement to coat all galvanized wire with a preservative compound immediately after erection and not to confine the extra protection to nozzles only.

I am glad of the opportunity of dealing further with the question of telephone transmission, as it is not possible to elaborate every point in a paper which must be kept within reasonable limits of length. Working on Sir William Preece's formula, it would be necessary to use copper conductors weighing 40 lb. per mile with solid paper insulation to have satisfactory transmission over a line 40 miles long, while 20-lb. conductors would be sufficient on a 30-mile line. Of course this assumes that the wires are laid up in pairs in accordance with the best modern practice. I have had some experience, similar to that mentioned by Mr. Medlyn, of the difficulty of telephone working on a big cable network. The difficulties can be and have been overcome on modern cable systems,

and there are now several successful telephone lines in use. The solution of the problem is one that requires a good deal of experience.

I have met the difficulty of Mr. Richards and other engineers in regard to Appendices III and IV by working out the two examples which appear at the end of my reply to the London discussion. In regard to rigid clamps, I am still of opinion that they are undesirable; the two instances given in my paper, and also the experience of rigid supports on tramway trolley wires, confirm this. In addition to this, the rigid clamp is an expensive article and can be readily displaced at much less cost by a flexible wire binder such as is illustrated in Fig. 8. Mr. Richards and another speaker misunderstood the lantern slide showing the conversion of the suspension of a telephone cable. Usually the cable may be attached to the suspender cable while on the ground by means of the Elder hangers and then the combination is strung up. I paid close attention to the cable sling described by Mr. Richards. I think his lantern slides showed quite clearly that the hanger is only used—and can only be used—for slinging up cables protected by jute along which the hanger would not slip, and that it was quite unsuitable for use with a small-diameter plain lead-sheathed telephone cable. I would refer those who are further interested in this question to the remarks by Mr. Vernier in the discussion before the Newcastle Local Section.†

YORKSHIRE LOCAL SECTION, 14TH JANUARY, 1914.

Mr. Johnson.

Mr. T. B. JOHNSON: The author states (page 179) that "an A-pole is about $4\frac{1}{2}$ times as strong as a single pole comprising one of the legs," and that "an H-pole without trussing tackle is about $3\frac{1}{2}$ times as strong as a single pole comprising one of its legs." The use of A- and H-poles respectively is of great importance, and I should be glad if the author would say whether the figures in regard to H-poles have been obtained by actual experiment or by calculation. In the case of A-poles the figures have presumably been obtained from the paper contributed by Mr. Wade to the Institution in 1907.† In view of the fact that A-poles are stronger as well as cheaper than H-poles, and that the wind pressure on them is smaller, it would be interesting to learn why H-poles are being used extensively, especially at angles (see page 184). In this connection it might be pointed out that the H-poles shown in the paper bear a strong resemblance to those given in the Post Office Technical Instructions, No. XIII. The Post Office practice, however, is largely governed by the fact that it is necessary to provide for a large number of wires in a square. This requirement does not exist in the case of poles for power wires. The flexible telephone binder illustrated in Fig. 11 is suitable only for light bronze wires. Copper wires, of say 100-lb. gauge, should be bound in by means of flattened copper tapes and binders, the tapes preventing injury to the line wire. I think Fig. 14 should be amended so as to show two pairs of insulators. If wires were "made off" on the same insulator, the losses due to leakage in wet or foggy

weather would be very considerable, especially in smoky districts; and as the circuits are already subject to disturbance owing to the proximity of the power wires, it is desirable that leakage should be prevented as far as possible. I should be glad if the author would state the highest voltage in connection with which the triangular guards illustrated in Fig. 16 have been used, and also whether they are intended for use on high-tension or medium-pressure lines. Can he also say whether they have been used at crossings over railways, roads, or Post Office wires? A glance at Fig. 17 will show how desirable it is to avoid combination poles as far as possible. The Postmaster-General has expressed his willingness to place his wires underground (at the cost of the power undertakers) in those cases where only local wires are affected. Would it not be possible to come to an arrangement for the Post Office wires to be placed underground in those cases where telegraph or short-distance telephone wires are affected, and for the power wires to be placed underground where the Post Office poles carry long-distance trunk circuits and it is necessary to retain a high "speaking efficiency"? The difficulties which faced power engineers a few years ago in placing their wires underground seem to have been surmounted to a considerable extent, and the use of underground power mains now appears to be less objectionable and costly than the erection of elaborate joint poles.

Mr. W. LANG: I should like to know whether in view of the steady increase in the use of overhead lines any steps have been taken to ensure the least possible obstruction in open country. That is especially important in view of

* See page 316.

† C. WADE, "The Use of Wooden Poles for Overhead Power Transmission," *Journal I.E.E.*, vol. 39, p. 304, 1907.

• See page 306.

possible future developments as portrayed by Dr. Ferranti in connection with the transmission of power. What has been done up to the present is the merest bagatelle compared with what would be required if anything approaching Dr. Ferranti's forecast were attained; and this would necessarily mean a careful lay-out of the overhead network so as to prevent the country's assuming the appearance of a gigantic spider's web. Then again, the construction shown in Fig. 17 on page 192 may be a sound piece of engineering work, but it is by no means beautiful from any other point of view; especially when one considers that the same end could be reached by going underground at such a point.

Mr. J. E. STORR: I think the author's opening remarks with regard to the relative costs of overhead line construction and cable work for voltages up to 3,000 should not be passed without challenge. I cannot agree that cables are even generally cheaper than overhead lines up to pressures of 3,000 volts; and to confine the use of overhead lines to higher pressures would be most detrimental to the cheap supply of energy in districts where an extra-high-tension supply is not warranted by circumstances. I have in mind lines operating at a pressure of 2,000 volts serving as distributors from extra-high-tension sub-stations where cables would be prohibitively costly. As to the factor of safety on the conductors, the author holds that the present factors are necessary for power circuits, and suggests that the wires of the Postmaster-General are not on the same footing as power wires, as the danger to the public due to falling wires is not the same. This may be so in many places, but with the extensive use of aerial conductors for traction and power distribution there is a very real danger from contact between telephone and power wires. The factor of safety on the Post Office wires should be increased if the present factors for power wires are to be retained. As the matter stands to-day, the guardings have to be erected about power lines to ensure that not only power wires cannot fall on the Post Office circuits, but that broken telephone and telegraph wires cannot foul the power lines when the former get adrift.

In the description of typical overhead lines the spacing of the conductors is given as 5 ft. for a pressure of 20,000 volts and 4 ft. for 11,000 volts. These figures appear to be unnecessarily high, and must involve an annual charge for line losses which materially reduces the advantage of a saving in capital expenditure by the use of overhead lines. The figures given at the bottom of page 185 are quite sufficient; in fact there are a number of 11,000-volt lines which are working quite satisfactorily at 2 ft. 2 in. centres. I think there is a tendency to extravagance in some designs, and the factors of safety adopted are altogether unnecessary. This is perhaps due in some measure to the wide difference in cost between aerial and cable work; but the tendency must be checked or else the advantages of reduced distribution costs will be much less than they might be. At the same time, first cost must not be the pre-eminent consideration, as absolute reliability of service is of paramount importance and must have first consideration. The author recommends H-poles for angles, but I think that A-poles should be given preference on account of the greater stability of the latter. The design of the pole equipment has to have full consideration when the type of pole is considered, but I think the very effective

strutting of one pole to the other and the lock obtained by the oak key gives the A-pole a strength which cannot be obtained by any amount of cross ironwork, tie-bolts, etc. Unless very deep gins are cut to receive the channel arms and extra heavy brace-work is used, the small bearing surfaces allow racking of the H-poles when the latter are used at angles, and an unstable structure is the result.

Under the heading "Insulator Pins and Fixing," no mention is made of the method of fixing insulators by metal thimbles. These thimbles are threaded inside to Whitworth standards and cemented into the insulators by the insulator manufacturers when the insulator parts are set together. The thimble is thus fixed by expert workers and a good job is ensured, and all that is necessary during erection is to screw the insulator on to the pin—thus skilled labour as required for cementing in pins, and more especially for oiled twine fixing, is unnecessary. A great advantage due to metal thimbles is the easy removal of a damaged insulator, an operation which can be performed in any weather in a few minutes. I think in cement fixing it is difficult to set insulators to stand upright on the pins. In the case of twine-wrapped pins unless the packing is done very effectively the cushion effect is lost, and small movements of the insulator on the pin, particularly at angles, soon burst the insulator due to the unequal strains.

Under "Guarding of Conductors," the author mentions an earthing bracket fixed only 8 in. away from the conductor and 12 in. out from the insulator. Is the distance out from the insulator adequate? Would not a line falling clear 12 in. before touching the bracket; also 8 in. from wire to bracket appears to be more of a menace than security, as large birds would no doubt set up an "earth" if they got on the bracket.

With regard to the alternation of solid or stranded conductors, where any doubt exists as to the corrosive effect of the atmosphere on conductors, stranded wires should be avoided owing to the percolation of fumes into the interior of the lines; to some extent the effect of such fumes is reduced externally by rain washing, etc., and on examination a false sense of security is obtained. If a 4.0 S.W.G. wire is not large enough I should prefer to run more than one circuit to avoid stranded conductors of any metal under doubtful circumstances. I should like to ask the author if he has observed any great difference between the snow and ice loading of conductors in the case of stranded and solid conductors. In conclusion I endorse all that the author has said with regard to the difficulties in connection with wayleaves, and I think the necessary steps should be taken by this Institution, or by a combination of the parties most concerned in this matter, to obtain greater freedom in wayleaves and consents. If it is only possible to establish Courts as on the Continent to arbitrate promptly in cases of difficulty, it will be a great advancement.

Mr. W. H. WRAITH: In connection with the author's remarks on page 190 with regard to telephones and bare telephone wires, I should like to point out that there is a considerable mileage of bare telephone wire fixed on the power poles in this district, and that instead of using high-tension telephones, well-designed protective gear is connected on the line side of the 1-1 transformer, thus effectually earthing the line in the case of a short-circuit

Mr. Storr.

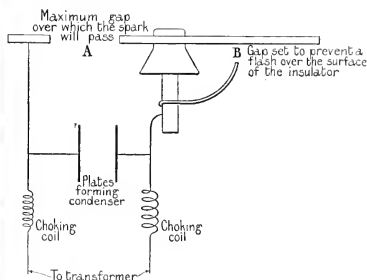

Mr. Wraith.

Mr. Waitt from the power lines. This not only protects anybody using the telephone but also protects the instrument itself, thus taking the element of danger one complete step further away from the operator and allowing ordinary long-distance loud-speaking telephones to be used in every case.

Mr. W. E. BERNARD: In the Board of Trade Regulations the stress to which a wire is subjected due to wind and ice is taken as proportional to the diameter of the wire. It is well known in aeronautics that with a small wire the stress due to wind is by no means proportional to the diameter, being much larger in proportion on small wires; and also that if the wire is in a state of vibration the stress is greatly increased. Further, the loading due to ice is not at all proportional to the diameter of the wire; in fact the diameter of the wire has little influence on the thickness of the ice that is formed. As the stresses which cause wires to break down are almost invariably due to a combination of ice and wind, it follows that any calculation based on the assumption that the stress is proportional to the diameter of the wire is by no means in accordance with the facts, and that a small high-tension wire erected on this basis would be relatively much weaker than a large low-tension wire. Considering the relative stress on wires due to wind and ice together, it will be seen that instead of the actual factor of safety on an average power line being about double that on an ordinary telegraph line, as would appear from the Board of Trade constants, the factor of safety is actually more like 5 or 6 times that of the telegraph wire. Whilst this shows the impracticability of bringing the telegraph line to a point where it can withstand the severe conditions of wind and sleet that cause so much trouble, it also shows that the tendency would be to make with the further development of overhead distribution the heavy low-voltage line still stronger and the weak, light high-tension lines less safe than they ought to be. I think that a more accurate method would be to base a formula on accurately observed results on a wire of about $\frac{1}{2}$ in. diameter, obtain the constant from this, and then calculate the permissible loadings for other sizes, assuming the stress to vary as the square root of the diameter instead of in direct proportion to the diameter. This should give approximately the same degree of safety throughout a fairly wide range of sizes of wire under the conditions which actually cause breakdowns.

Another point is with regard to high-tension insulators, which, although designed to flash over rather than puncture, do in service occasionally puncture, usually during a thunderstorm or when a high-frequency surge or sudden shock occurs due to a short-circuit or some other transient disturbance on the system. It is evident that there are at least two ways in which an insulator may break down, the first being analogous to a straight shear where the breakdown occurs simultaneously throughout the substance of the insulator, and the second a progressive disruptive effect which travels through the insulator somewhat in the manner in which a crack caused by a sharp rap travels through a piece of glass. The first occurs at the ordinary frequency, and the second is due to sharp shocks such as may be caused by the high-frequency disturbances just referred to. Some interesting experiments on this subject have been carried out by Messrs. L. E. Inlay and P. H. Thomas.² It was found that the puncture strength in the

case of a high frequency had little relation to the strength Mr. on normal frequency; for instance, an insulator that Burnard. withstood without puncturing under oil a pressure of 250,000 volts at 60 cycles, punctured at a pressure of 100,000 volts, the frequency being estimated at 1 million—a frequency quite comparable with the jerk due to a lightning discharge in the vicinity of the wire. These experiments, and the fact that insulators actually puncture in service in preference to flashing over, show that the tests as outlined in the appendix to the paper still leave in many cases a weak spot untested. I think the tests outlined should be supplemented by one designed to test the above point, since it is quite certain that insulators have to stand in service these sudden shocks, and should be designed accordingly. It is quite a simple matter to make such a test; all that is required is a small length of conductor fastened to the insulators in the ordinary way, and to discharge on to this short length from the testing transformer over a gap of a length that the testing pressure can just jump. Under these conditions there is of course a very sudden jerk at the instant that the spark occurs. This stress is reversed just as rapidly when the wave arrives at the reverse peak, and under these condi-

tions it is theoretically possible to get twice the maximum value of the peak on the insulator, i.e. with a testing pressure of 70,000 volts (R.M.S. value) it is theoretically possible to get a pressure on the short length of conductor of about 200,000 volts; but this, of course neglects all losses and the resistance in circuit, and there is no doubt that the actual value is much less. It might be thought that even though this pressure is considerably less than the theoretical maximum the increase of pressure was the cause of breakdown under this test; but this is hardly the case, since it is the relation between the puncture and flash-over values, which ratio is evidently very different under these conditions from that under the conditions of normal frequency. The diagram herewith shows the arrangement for making the test on very high voltages. The arrangement of choking coils and condenser is designed to protect the transformer end-turns from the heavy shocks that occur under these conditions, and is substantially the same in principle as that adapted by Messrs. Inlay and Thomas, except that those experimenters omitted the choking coil

² *Electrical World*, vol. 60, p. 1355, 1912.

from the earthed side of the transformer—which I think is not justified, as the pressure between the end-turns is just the same on the earthed as on the high-tension side of the transformer. For testing pressures below 50,000 volts it is doubtful if the condensers and choking coils are at all necessary for protecting the transformer, a simple resistance in the primary of the transformer so as to limit the current when the spark occurs being sufficient; but this of course depends to some extent on the transformer itself, since different transformers vary in the relative strength and capacity of the end-turn insulation.

Mr. H. E. YERBURY: The equipment of high-tension overhead lines has almost reached the standardized stage, and as many power distribution schemes are only commercially possible with overhead transmission the greatest obstacle appears to be the granting of wayleaves. I am inclined to think that greater progress would be made in that matter if aesthetic considerations were not divorced from strict utilitarianism. As mentioned by the author, public roads appear to be suitable for the erection of poles, but I think that perhaps adjoining railway track would in many cases be preferable, assuming of course that other wires would not be seriously influenced by these high-tension lines. It would undoubtedly be most satisfactory to aviators if it could be arranged for all extra-high-tension lines to be erected on or adjoining main roads and railways, leaving as far as possible the open country for either voluntary or involuntary descents. As reinforced concrete poles are not mentioned in the paper, I should be glad if the author would give his views with regard to these, as I have seen many designs of such poles on the Continent and should like to know what are the disadvantages apart from their weight. I cannot agree with the author that the deterioration and maintenance of steel tramway poles is high, for I have recently had occasion to remove many centre tramway poles after a life of 12 to 13 years, and they were found to be practically as good as new poles. It should be mentioned that all the poles were fitted with bases, which I think adds greatly to their life, as the point of corrosion is generally found at the surface of the road. The average cost of painting was from 5s. to 6s. per pole; these poles were painted every three years, and the bases and collars were raised for that purpose. As atmospheric and other conditions in England are favourable compared with other countries, I think it is only a question of time when extra-high-tension lines of higher voltage will be run in country districts, but I believe underground cables will still hold their own in all cities and fair-sized towns. Judging by the overhead work which is to be seen in foreign towns, I feel thankful that we have a reasonable Board of Trade to regulate our schemes in this country. I heartily endorse the author's suggestion that representations should be made by our Institution to the Board of Trade on matters requiring revision, as is done by the Tramway Associations on matters relating to tramways.

Mr. E. V. PANNELL (*communicated*): Considered in connection with others which have been presented during the last few years, this paper affords evidence that overhead power transmission in England is now being treated as an everyday engineering problem and not as an undesirable and temporary makeshift. In agricultural districts I believe much could be done by way of selling electrical apparatus

and energy to farmers. In Ontario, for example, electricity is distributed by overhead mains to the farms, where it is used for milking and threshing machines and is also beginning to displace steam for ploughs. Undoubtedly after manufacturing and mining districts have been supplied there is reason to believe that the agricultural communities will prove the next to be persuaded of the advantages of electricity supply. With reference to the author's remarks on steel poles at the foot of page 179, he surely does not mean to suggest that the formula given on page 180 represents the whole of the stress on the pole, and that no allowance need be made for wind and ice. This can only be neglected where the wires are of considerable size and θ is nearly 90 degrees. Possibly the factor of safety of 4 is meant to cover all the non-calculated stress; this would bring the design into line with the structures used in America, where all the stresses are worked out and a factor of safety of 2 or 3 is employed. The table in Appendix XI showing the maximum angle of swing of the wires is interesting but should not be looked upon as inflexible. For one thing, the wave front of a wind is not often a plane; the pressure will therefore vary throughout the span and the wire will not hang in the form of a catenary. This will cause ripples to be set up along the wire. Further, the direction of the wind often deviates from the horizontal, especially over ravines where an upward vertical gust is not uncommon and frequently gives trouble where insufficient spacing has been allowed. If the wind pressure has a downward component it will of course increase the sag, as it will be adding to the apparent weight of the wire.

I was interested in the author's suggestion that a 70 per cent yield-point should be specified for aluminium conductors. As a rider to this a standard method of test should be specified; for I have found tests on aluminium wire to give very varying results according to the method adopted. Short specimens of wire tested by the "point to point" method on a beam testing-machine certainly give a misleading value for the modulus of elasticity, the latter always appearing too low. It is surely time that the Engineering Standards Committee should give their attention to the formulation of a specification and tests of aluminium wires and cables. Further to this I most heartily second the author's proposal that a Transmission Lines Committee of the Institution should be appointed. Such a committee, working along similar lines to those of the National Electrical Light Association in America, could accomplish work of considerable value to all engineers and manufacturers associated with our industry.

Mr. B. WELBURN (*in reply to the discussions before the Newcastle and Yorkshire Local Sections; communicated*): After each discussion I answered fully most of the points that were raised. Some of them had also been brought up at other meetings and have already been replied to; I hope members will therefore be good enough to look through the replies in the *Journal*.

Mr. Hunter, Mr. Storr, and Mr. Vernier have dealt with various aspects of the general comparison between the cost of cables and of overhead lines. Mr. Hunter and Mr. Vernier have raised a question of importance in regard to cable design which falls rather outside the scope of the paper. It is quite true that the Engineering Standards

Mr. Weibourn. Committee's specifications for cables were prepared several years ago and before high-tension cable manufacture was so well understood, but no dielectric thicknesses have ever been standardized for alternating pressures above 11,000 volts. It is permissible to point out that the cable specifications of the Engineering Standards Committee are not obligatory on anybody, and it is open to any engineer to specify other dimensions for his cables; but it must always be borne in mind that any reduction in dielectric thickness also inevitably means a reduction of the factor of safety. Possibly the time is approaching when the Engineering Standards Committee can profitably undertake a revision of their cable specifications, because the conditions on modern systems are changing to the advantage of the cable manufacturers. For example, alternators with a sine curve can now be obtained, automatic balanced protective devices such as the Merz-Hunter and Merz-Price are coming into common use, and the design and quickness of operation of high-tension switchgear have been much improved. On modern supply systems working at pressures up to 11,000 volts it seems quite possible that dielectric thicknesses might be reduced; but I think it would be difficult to make out a good case for doing so on any alternating-current system supplied by plant of old design and having a bad wave-form. It may not be out of place to recall the fact that approximately one-half of the capital invested in the electric supply business in the United Kingdom has been spent in cables, and it is without doubt mainly due to their reliability that electricity supply has been able to obtain the confidence of the public. I am very interested in Mr. Hunter's theory as to the beneficial action of paper-insulated cables when used in conjunction with overhead lines. Apparently he thinks that they are equal to Mosciicki condensers in their ability to relieve the system of high-frequency disturbances of the order of, say, 100,000 per second, and much superior to them when frequencies of the order of 500 to 1,000 per second have to be dealt with. There is much to be said for Mr. Hunter's view, but nobody yet knows what is the maximum loss in watts that can be permitted in the usual dielectrics without causing injury sooner or later. Heating of any dielectric is always objectionable, and how far it can be carried must be decided by future investigations.

Mr. Vernier's amplification of the particulars given in the paper of the Elder suspension system for lead-sheathed cables is most valuable and will be carefully noted by all those who are interested in this question. The discussions have shown that strong views are held for and against the use of bare telephone wires. Where they are used, I understand the Home Office is enforcing the use of some for n of high-tension telephones. Money spent on apparatus which can be relied on to protect the operators under all circumstances is money well spent.

Mr. Johnson queried the advisability of using the arrangement shown in Fig. 14. It was intended to be diagrammatic, and I quite agree that in practice the leakage distance should be much longer than that indicated. This arrangement can be used in clean country districts; but where there is much coal-dust, etc., two pairs of insulators may be used for the transposition. The triangular guard illustrated in Fig. 16 was used on a 6,000-volt three-phase line across country quite near to London.

Mr. Weibourn. With suitable additions it may be used for railway, road, and Post Office crossings. Fuller particulars of it are given in a paper read by Mr. A. P. Trotter before the Post Office Electrical Engineers in London on the 20th January, 1914, and I understand that it is also to be read again shortly in Leeds before a joint meeting of the Post Office Engineers and this Institution. I think most power engineers now prefer to cross Post Office trunk circuits by means of underground cables. It is usually cheaper and more sightly to do so than to arrange for combination poles, and it has been found, as pointed out by Mr. Hunter, that there are advantages in having some insulated cables in high-tension circuits. So far as I know, no thorough investigation has ever been made into the strength of H-poles with and without trussing tackle. The figure of 34 given for an H-pole is the result of calculation and much experience, but there are no reliable data as to the exact additional strength obtained by adding one or more sets of trussing tackle. I suggested to Mr. Wade at Leeds that he would confer a boon on the industry if he would carry his standard work on A-poles further and do the same for H-poles. H-poles are frequently employed at corners on transmission lines in order to preserve the spacing of the conductors. They are much more sightly than A-poles, which may have to be provided with specially long arms.

Mr. Storr mentioned the earthing bracket on page 101. It has been found satisfactory in practice, but I think it is clear it should only be used on a high-tension line working with an unearthed neutral. In regard to the collection of snow, I think a stranded conductor will necessarily begin to gather it earlier than a solid one. This question is linked with the one which was raised by Mr. Vernier about the difference in behaviour between short and long spans, and it has been dealt with already in the Manchester discussion, as has also Mr. Burnand's valuable suggestion about testing insulators under high frequency.

I think Mr. Pannell has rather misunderstood the reference on page 179. (B) belongs to Section I. Section II deals with "stress on poles due to change in direction of wires," and applies both to wood and to steel poles. The probable loading of wires by snow and ice must of course be taken into account in calculating the stress on the poles, but in British practice it does not appear necessary to make further provision for ice and snow on the poles themselves. The factors of safety for wood and steel poles take care of this loading. The remarks on the varying behaviour of wind go to confirm the views expressed elsewhere that short spans are more affected by high winds than long spans are. I am sorry that Mr. Pannell was unable to be present at the reading of the paper as I dealt more fully with the question of the 70 per cent "limit of proportionality" or "elastic limit." This point is lower on the curve than the "yield point." The tests referred to have been made by a careful engineer with a Dennison testing machine on 5-in. and 6-in. specimens of aluminium, and the results obtained are remarkably consistent for the sizes of wires in the table on page 185. Subsequent tests on aluminium strand tend to show that the limit of proportionality on strand is rather higher than on single wires, and further investigation is being undertaken to settle this important point definitely. For the present I think a standard specification for aluminium could better be dealt

with by the suggested committee of this Institution than by the Engineering Standards Committee.

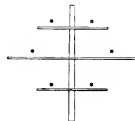

The discussions have brought out varying experiences with steel poles. Mr. Yerbury's results after 12 years' use of poles in Sheffield have been quite satisfactory, and presumably his tramway tubular poles are not made of high-tensile steel. Mr. Elliott's experiences agree with mine, and he is in no doubt that steel poles should be avoided whenever possible. It is always to be remembered that our climatic conditions are often unfavourable to steel, and I know of one important railway where even the steel rails have to be painted in order to prevent unduly rapid corrosion. In a humorous vein Mr. Ward has asked me for an estimate of the life of the steel towers at the River Blyth. My views on the general question of steel poles have not been disguised, but I think it would be impolitic to give a specific answer to his question. This is a particular case where I do not doubt the poles will receive special care and maintenance.

Mr. Elder has made a powerful appeal to designers and erectors to study the general appearance of overhead lines and to make them as little displeasing as possible to the eye. It is to be hoped that this will not pass unheeded, as there is certainly plenty of room for improvement. Wayleave difficulties are often responsible for a slovenly appearance. If these could be overcome and lines thus run straight instead of following nearly every fence, the gain in appearance would be immense. Mr. Elder's confirmation of the great need for studying details is timely. His own work on the suspension of lead-covered cables of small diameter has been of the greatest benefit, and has done much to make their use possible on overhead lines. Mr. Bridges and Mr. Gillott have given whole-hearted

confirmation of this view. Mr. Beard's query is quite to the point. Lead-covered cables have many excellent features, but freedom from collection of snow is not one of them. In the slides which were shown most of the snow had already fallen from the insulated telephone cable.

I have much sympathy with Mr. Ward's suggestion that heavy terminal boxes should be allowed to rest on the ground during jointing instead of being placed aloft on terminal poles. It would facilitate the work and be much safer for the workmen, and I hope that engineers will specify that the work shall in future be done in this way.

In reply to Mr. Gregory, I prefer the arrangement of the conductors of a three-phase line in one horizontal plane to that in a vertical plane. There is certain evidence (which will probably be made public later) to show that the sum of the wind pressures on the horizontal wires is considerably less than that on the vertical wires. For duplicate-circuit lines an excellent arrangement of the wires is shown in the accompanying sketch.

Mr. Porter's experiences with telephones are very valuable; the only entirely satisfactory solution of his difficulties would appear to be to use high-tension telephones throughout.

INSTITUTION ANNOUNCEMENTS.

LENDING LIBRARY.

The Lending Library Catalogue is issued with this number of the *Journal* to members residing in the United Kingdom.

ASSOCIATE MEMBERSHIP EXAMINATION.

An examination will be held on Friday and Saturday, the 1st and 2nd May, at the Examination Hall of the Royal Colleges of Physicians and Surgeons, Queen-square, Bloomsbury, W.C. Should a sufficient number of candidates make application, arrangements will be made for the examination to be held concurrently in local centres.

Entry Forms, which must be returned not later than the 2nd March, may be obtained together with the Examination Regulations on application to the Secretary of the Institution.

BEIT SCHOLARSHIPS FOR SCIENTIFIC RESEARCH.

The second election of Fellows will take place on or about the 15th July, 1914. The Fellowships, of which not more than three will be awarded at this election, will be tenable at the Imperial College of Science and Technology, South Kensington, and will each be of the annual value of £150. The tenure of a Fellowship is for one year, but it may be extended by the Trustees for a further period not exceeding one year. Candidates must be under 25 years of age on the date of election. Applications will be received up to the 15th April, 1914, and must be made out on special forms, which, together with any other particulars in respect of the Fellowships, may be obtained, by letter only, addressed to The Rector, Imperial College of Science and Technology, South Kensington, London, S.W.

SUGGESTED METHODS OF IMPROVING THE TELEPHONE SERVICE.

By W. AITKEN, Member.

(Paper first received 20th June, and in final form 6th October, 1913; read before the NEWCASTLE LOCAL SECTION 6th February, 1914.)

COMPLAINTS BY PUBLIC.

Grave complaints are being made regarding the efficiency of the telephone service. Whether these are justified or not it is rather difficult to say without a very careful study from the inside. The old National Telephone Company received a fair share of complaints and abuse, and the Post Office have taken that over—with perhaps something added to it—along with the plant and other effects of the Company.

The complaints are not very specific, but they may be tabulated thus:—

1. Failure to give service.
2. Charging for service that has not been given.
3. Mistakes in operating.
4. Operators incorrectly reporting lines engaged.
5. Premature severing of the connection.
6. General slackness on the part of the operators.

The first complaint cannot be dealt with by electro-mechanical means, and this paper therefore takes no further notice of it. The second to the fifth complaints inclusive, however, contain features on which this paper has considerable bearing, and the author hopes to put forward suggestions for methods of working that will eliminate many of these troubles directly or indirectly. Complaint 6 is perhaps the most generally believed in and the most difficult to rectify. This assumes that the passing from the service of the Company to the Post Office has made the operating staff less conscientious and less faithful in the performance of their duty. If this be so, it can be rectified in time by discipline and careful supervision.

After carefully reviewing the systems in use and the operation of the same, the author has come to the conclusion that the plant is not as efficient as it might be, and some suggestions are here made for improving the efficiency of the plant and enhancing its value.

It must be recognized that the full automatic or machine telephone system must gradually replace the girl-operated system, but for economic reasons this cannot be introduced as quickly as telephone administrations would like, or as quickly as the public might demand, neither could the firms capable of manufacturing this equipment cope with the supply for the whole country within a period of from six to ten years. That system would therefore be outside the scope of the present paper.

An endeavour is here made to suggest improvements that can be introduced in a comparatively short space of time, and at a small increase of cost, on switchboards that are of modern pattern.

RESPONSIBILITY FOR SERVICE.

There are two parties responsible for the efficiency or inefficiency of the telephone service, viz. the operators at

the central exchange and the subscriber's operating staff. The operator answers a call, tests the line wanted, and if the latter is idle completes the connection. In a manually operated system these duties are fundamental. In addition, at present the operator on receiving certain signals withdraws the plugs. If, however, the position is very busy, the operator may answer one or more fresh calls before withdrawal, with the result that between the time when the calling subscriber replaced his receiver and the operator withdrew the plugs that line would test "engaged" to any other caller. Again, either line desiring a second call during that period would cause a supervisory lamp to glow, and in the case of the called subscriber this lamp is on a position where he cannot be answered.

These weaknesses the author proposes to rectify by giving the equivalent of automatic disconnection, the instant removal of the engaged test when the subscribers replace their receivers, and the instant reconnection of the calling lamp to each line, so that the operator gets a definite calling signal if the receiver is replaced and then immediately removed.

The subscriber's staff can also greatly interfere with the efficiency of the service by operating it incorrectly. If every line ended on one telephone the service would be ideal as far as the subscriber was concerned, but he frequently has a switch for one extension line, or several lines on a switchboard, and with these he is given facilities for upsetting the service if he does not conform carefully to the instructions provided. The connection will probably be put through promptly, but when the ring-off signal is received from the extension line it is not acted on instantly, with the result that if the "central" operator has another call for the same subscriber, instead of getting the "main" station she gets the extension, or should the extension desire to call the main station the exchange will be called and the operator will find that she is not wanted. Obviously all these proceedings react to spoil good service. Usually the operating is left to the office boy, with the foregoing results. The devices described below will after a call cause the restoration of all apparatus to its normal condition to be automatic.

AUTOMATIC DISCONNECTION ON MANUAL SWITCHBOARDS.

An invention which can speed up existing systems and make the essential and responsible operation on which the efficiency of the service most depends *automatic* and beyond the control of the operator is worthy of the gravest consideration. In addition to automatic disconnection each line tests idle immediately the receiver is replaced, the line lamp is instantly reconnected with its line, and the called subscriber is guarded against the caller not replacing his receiver promptly.

When the connection is through two or more exchanges

the advantages just mentioned are secured, and also the junction line is instantly released and made available for another connection. The carrying capacity of the junction lines will thus be increased, and in all probability the A operators' load can also be increased.

The conversion of an existing common-battery switchboard to automatic disconnection is a comparatively simple matter, it being necessary only to alter the connecting cord circuits by fitting in place of the lamp a special relay in the local circuit of the answering cord supervisory relay, and similarly another special relay in the local circuit of the calling cord supervisory relay, also adding two extra springs to the speaking key. On the junction circuit one cut-off relay of a simple pattern is required. Various modifications will be suggested to meet different conditions.

Lamp signals.—Preferably the lamp signals should be read in a method somewhat differently from that at

suffering in the slightest. The alteration of the A position is of the greater importance.

"A" position circuit.—When automatic disconnection is to be introduced on the system using repeater coils, it will probably be found advantageous to introduce the cut-off relays in the local circuits of the supervisory relays. If the cut-off relays are made to take the place of the supervisory relays they must be similarly shunted, and might therefore be affected adversely by the variation of the line resistance. The local circuit method will be found the simplest and most economical method of converting an existing plant.

Fig. 1 shows an "A" position cord circuit so equipped. Cut-off relay D is connected in the local circuit of the shunted relay S', the winding of which is connected directly in the line conductor. This relay is connected exactly as in ordinary practice, but now controls the cut-off relay instead of a supervisory lamp. All conductors from the plug AP are open on the relay D. The sleeve

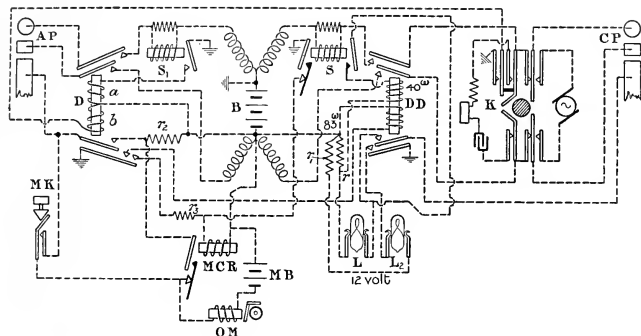

FIG. 1.

present adopted. Usually a lamp associated with each line glows as a clearing signal. With the author's system it is not essential to withdraw the plugs instantly, as they have been rendered electrically inoperative when the receiver is replaced, and he therefore prefers that certain lamps associated with the cords should glow during the period of connection. A supervisor will then appreciate the condition of the operator's load much more readily, as a glowing lamp will indicate a live connection. Plugs, whether in their sockets or in multiple jacks, having non-glowing lamps in front, are available for instant further use. The glowing lamp will take less current than the shunted lamp at present used. For the same reason the junction lamp should also preferably glow during connection, the line being instantly available when the receivers are replaced, whether a plug is in a socket or a jack.

The benefits of the system are felt immediately after the first cord circuit is altered, either on a junction or a subscriber's position, so that the change-over may be gradual and can be carried out without the service

conductor has a parallel connection to the meter key, which is also normally open. Relay D is double wound, one winding being in the local circuit of relay S' and the other in a local circuit controlled by two extra springs to be fitted on the speaking key. The calling cord relay DD opens all the conductors to the plug CP normally, and is controlled in the local circuit of relay S. When the present method of registering calls is retained, relay S is unaltered and is connected in every way as described for S'. In the diagram, S is shown with a contact which momentarily earths a circuit for automatic registration and then opens the circuit again. Relay DD is double wound, one coil being in the local circuit of relay S and the other being completed by extra springs on relay D, so that relay DD is energized and controlled by D, and only when relay D permits is relay DD under the control of the station called for disconnection purposes. To prevent relay D, by the action of the calling subscriber, irregularly or unduly holding relay DD against the called party, the winding of DD controlled by relay S is a shunt across the

supervisory lamp L_s . When therefore relay S is de-energized by the called subscriber moving the switch-hook, it opens the shunt circuit so that the lamp L_s glows and calls the operator's attention to the irregularity. As long as it is energized relay DD also completes a circuit of the lamp L_s . It will be noted that the transmission circuit, the line circuits, and the multiple are absolutely unaltered.

Operating.—When the operator answers a call by inserting the plug AP in the jack of the line calling, and presses-over her speaking key K to join up her telephone, relay D is energized, as a local circuit is completed from earth at the key K through extra springs, through winding b of relay D to the battery. All conductors are then joined through to the calling line and relay S is energized. This completes another circuit through the a winding of relay D so that it remains energized after the key K is moved to another position and opens the b circuit. Current through r_2 engages the calling line. Relay D being energized also completes a circuit from earth at the lower contact of D through the lower winding of DD to the battery, so that DD is also energized and the lamp L_s glows.

The operator tests the line wanted in the well-known manner and if idle inserts the plug CP . Ringing is done in the customary way. The supervisory lamp L then glows and continues to glow until the called subscriber answers.

When the subscriber answers, relay S is energized and completes the shunt circuit of the lamp L so that it ceases to glow. This coil is also the retaining circuit of relay DD .

The connection is now established. Should the calling subscriber replace the receiver, relay S will be de-energized and open the circuit of relay D . D will become de-energized and open all the conductors to the plug CP and the circuit of the energizing winding of relay DD . The calling line will immediately test idle and the line relay and calling lamp will be re-associated with it, so that another call can be sent in on the line lamp.

Relay DD will remain energized until the called subscriber hangs up his receiver, when relay S will be de-energized and open the circuit of relay DD so that all conductors to the plug CP are opened, and the called line will now test idle and the line lamp be re-associated with the line. The lamp L_s will cease to glow and the operator will know that the plugs are available for another call. Should the called subscriber be the first to replace the receiver, relay S will become de-energized and open the upper or shunt winding of relay DD so that the lamp L glows, but relay DD will remain energized by the circuit through the contact on relay D . If this lamp glows for an appreciable time the operator would challenge the calling circuit.

It will be readily appreciated that the plugs being rendered electrically inoperative it is not essential to withdraw them instantly, and they may be withdrawn at the convenience of the operator, or they may even remain in the jacks until required again for another connection.

For the same reason the negative clearing signal will be no disadvantage, as the connection is automatically disconnected by the subscriber, and it is believed that the lamps glowing during connection will be a valuable feature in continuously advising the supervisors of the condition of the operator's load.

REGISTERING TELEPHONE CALLS.

Manually operated.—The calls may be registered in the well-known manner by pressing a meter key, and in the modified arrangement this key may be pressed either during the connection or at the termination of the connection before the plugs are withdrawn. The answering plug third conductor is connected in parallel with a spring of relay D and a spring of the meter key, both being insulated normally. If registering is done during the conversation the operator's meter and extra battery are in parallel with the resistance r (about 200 ohms), but if after, there is no resistance, as the circuit is open at the springs of relay D .

Automatic registration: meters in exchange.—The automatic disconnection system lends itself readily to automatic registration in a simple manner, particularly if the meters are retained in the exchange as at present. The existing circuit with the meter in parallel with the cut-off relay remains unaltered. One additional relay, MCR (Fig. 1), is required, and may be called the meter control relay. This has springs so arranged that it gives a momentary contact when energized. An extra spring is added to the cut-off relay D to complete a circuit for relay MCR . The resistance r_3 in series prevents relay MCR pulling up when relay D is first energized. When the resistance r_3 is momentarily short-circuited, relay MCR is energized, and is then retained energized by the circuit through relay D . The supervisory relay S has springs so arranged that when energized a momentary earth is put on relay MCR as before mentioned. As relay MCR is then locked in a local circuit further operation of relay S will not affect the circuit again.

Operation.—When the calling subscriber is answered and relay D becomes energized, a circuit is completed from earth through the contact of relay D , resistance r_3 , winding MCR , to the battery. Resistance r_3 , however, does not pass sufficient current to energize relay MCR .

When the called subscriber answers by lifting the receiver, relay S is energized and momentarily shunts the resistance r_3 , and relay MCR is energized and remains energized because the current through it is sufficient for that purpose. Relay MCR on becoming energized momentarily completes a circuit from the main battery B , through the meter battery M , the operator's meter OM , the contact of relay MCR , the contact of relay D , to the third conductor of the plug AP and the jack of the calling line, through the meter to earth, so that both meters register one call. Relay MCR is not de-energized until relay D has opened its contacts, so that it is impossible for relay MCR to send another impulse on becoming de-energized when the springs again momentarily make an earth connection.

If thought desirable a key MK may be fitted so that the operator can send an additional impulse when the call is of greater value than one impulse.

Meters at sub-stations.—When the meters are to be fitted at the subscribers' offices two meter control relays are necessary for each cord circuit (Fig. 2). Relays D and S are altered as before described. Relay R (Fig. 2) has two normally insulated contacts, connected one to each line at the plug side of relay D . Relay R is in a local circuit completed through a contact on relay D , so that relay R is energized immediately after relay D . Momen-

tary contacts are then made with the lines, but, as relay R R is not energized, the battery is not connected. Relay R R completes a circuit for relay R R through resistance r_3 , which does not allow sufficient current to pass to energize it. Relay R R is made to de-energize slowly. The momentary contact on relay S energizes relay R R by short-circuiting the resistance r_3 . Relay R R is then held energized whilst the local circuit is completed through a contact on relay R.

At the sub-station the meter, which is made to de-energize slowly, is fitted normally in parallel with the speaking set. It may remain in parallel or be cut out of this circuit. When the relay part of the meter is energized in this circuit, a second or registering circuit is completed in parallel with the condenser, which is normally in series with the bell.

The operation is as follows:—When a subscriber makes a call, a circuit is completed through the relay winding of

meter registers and then falls away, so that the condenser is in series to prevent current flowing normally. The meter is de-energized slowly so as to allow of the impulse being received. The relay R R is made to operate slowly so that it will not become de-energized until the impulse has been sent by relay R.

Meters at sub-station and exchange.—The existing meter arrangement may be retained at the exchange, and a connection made to the back contact of relay R, which is normally open at relay R R, so that an impulse may also be sent through the exchange meter when the calling subscriber replaces his receiver.

JUNCTION WORKING.

Order-wire junction.—Fig. 3 is a diagram of a junction circuit in its simplest form showing only the features in connection with automatic disconnection. The special feature is the introduction of the cut-off relay R, on

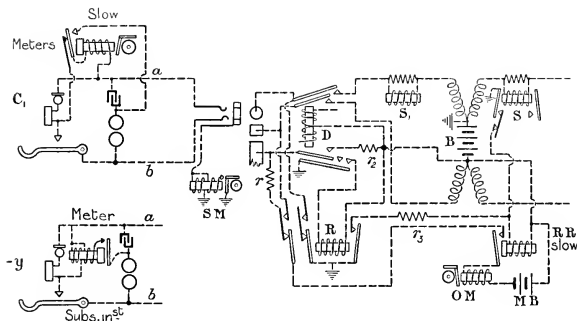

FIG. 2.

the meter in parallel with the speaking set, so that it operates to connect the registering circuit across the condenser and in series with the bell. The operator answers and connects relay D in circuit, and relay R is energized and causes momentary contacts to be made with the lines, but completes no circuits. Connection is made with the subscriber called, and, when he answers, relay S is energized and momentarily shunts resistance r_3 , so that relay R R is energized and is retained energized by the circuit through relay R contact. Relay R R completes no circuit when energized, as the circuit is open at relay R.

At the termination of the conversation, when the calling subscriber replaces his receiver, relay D is de-energized and opens the circuit of R. As relay R becomes de-energized its springs make momentary contacts, which complete a circuit from the batteries B and M B, through the operator's meter O M, the contact of relay R R, the outer contact of relay R, to the ring of plug A P, over line b, through the bell and meter to wire a, the tip of plug A P, to the other contact of relay R, to earth. The sub-station

which the three conductors of the plug P are normally insulated.

The four-wound repeater has the two windings on the line side connected through a condenser, which is shunted by the 12,000-ohm winding of a relay R. The repeater windings to the plug have the inner ends connected to the battery. One conductor to the plug has a supervisory relay R, in series (with a non-inductive shunt). This relay R, when energized, connects a low-resistance winding across the 12,000-ohm winding of relay R. Relay R completes the circuit of the cut-off relay R, so that it connects all the conductors through (with the exception of a break in the tip conductor). The back contact of the third conductor relay R, connects the operator's testing winding I C through a contact on the cut-off relay to the tip of the plug P, so that when the operator tests the line she may get a click in her receiver if it is engaged. The A operator must take up the line instantly it is allotted to her, so as to energize the disconnect relay and join up the B operator's testing circuit. To enable the B operator to

know that this has been done and that the test will be effective, a tone test device is connected in the circuit of the testing winding of her speaking set, by which she will get a low hum when she tests, if the cut-off relay is energized, on which the ordinary test will be superimposed. It is suggested that in a primary circuit of a coil and battery a suitable and distinctive tone would be received from a microphone, against the diaphragm of which a jet of air impinged. The cut-off relay also completes the circuit of a lamp, which glows until the cut-off relay is de-energized at the termination of a conversation.

Operating.—When an A operator receives a call for a line in another exchange, she asks for that number over a suitable order wire, and the B operator allots a junction to be used. The A operator has lifted the plug, such as C P in Fig. 1, and is waiting with her plug over the block of jacks appertaining to the exchange in question, so that she plugs in instantly. The 12,000-ohm relay R is then energized, and it in turn energizes the cut-off relay R₂. Relay R₂ joins the conductors through to plug P with the exception

the calling line receiver has not been replaced. If the calling line receiver has been replaced, the cut-off relay D D will also be de-energized, and will open all the conductors to the plug C P, so that relay R is de-energized. This relay opens the circuit of the B-position cut-off relay R₂, and in de-energizing it opens all the conductors to the plug P, thus rendering it electrically inoperative. The called line now tests idle, and its line lamp is re-associated with the line in readiness for another call. When relay R₂ becomes de-energized it connects up the operator's testing circuit at that relay, but it is opened at a contact of the cut-off relay. The lamp L (Fig. 2) ceases to glow and the plug P may be withdrawn.

Any junction may be allotted for another call whether the plug is in its socket or in a jack—if the lamp is not glowing. The junction is thus rendered available for immediate further use when the subscriber replaces his receiver. Although a plug remains in the outgoing jack at the one end, and the junction plug may be in a multiple jack at the other end, they have both been rendered elec-

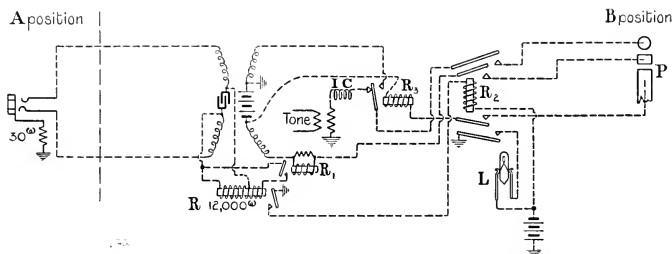

FIG. 3.

of the tip conductor, which remains open for testing purposes.

The B operator then tests the line wanted in the well-known manner, and knows by the faint hum received from the tone test device in series with the tertiary winding of her telephone set whether the line is engaged or not, that the test has been effective. The plug is inserted in the jack if the line is idle, and ringing is done in any of the well-known ways.

When the subscriber answers, the B operator's supervisory relay R₂ is energized, and this by putting a low winding in parallel with the high-resistance winding of relay R, actuates the A-position supervisory relay S so that the lamp L ceases to glow. When the junction plug was inserted, the sleeve relay R₃ was energized and cut off the operator's testing coil IC. The B-position lamp L glows during connection and until automatic disconnection takes place.

When the subscriber replaces the receiver after conversation, the supervisory relay R₂ at the B position is de-energized, and the low-resistance shunt on relay R is removed, so that the A-position supervisory relay S is de-energized, and allows the supervisory lamp L to glow if

trically inoperative by having all their conductors opened. The operators will withdraw the plugs as quickly as possible, but they may delay this until it can be done without interfering with the efficiency of the service.

Automatic calling on junctions.—When no order wire is used the insertion of a plug at the outgoing end automatically lights a lamp at the B position as a calling signal. Such a circuit is shown in Fig. 4.

The repeater, with its windings connected to the condenser and the battery, is exactly the same as on order-wire junctions, as is also the 12,000-ohm relay R and the supervisory relay R₂ at the B position. The relay R₂ does not directly control the cut-off relay R₂. All conductors to the plug P are normally insulated at relay R₂. The cut-off relay R₂ is double wound, one winding being completed in a circuit with the battery through an extra contact on the speaking key, which is closed when the operator presses over the lever to answer a call. The second winding has one side connected to the battery and the other to an inner contact of the cut-off relay, the associated moving spring being connected to the contact of relay R, the outer contact of the same moving spring being connected to the calling lamp and battery. When

the operator puts over the key to answer, relay R, is energized and cuts off the calling lamp C.L. A retaining circuit is then completed from earth at relay R, through the moving spring and the inner contact and winding of R, to the battery, so that when the operator cuts off her telephone the cut-off relay R, will now be controlled by relay R. A supervisory lamp S.L. is connected in parallel with the retaining coil of the cut-off relay, so that it glows as long as this relay is energized. The speaking and ringing key K is connected between the contacts of the cut-off relay and the repeater.

Operating.—When the A operator has a call for a line in another exchange she tests in the well-known manner for an idle line, unless a visual test or other device is provided to indicate what lines are engaged. When the plug, such as C.P. (Fig. 1) is inserted, the 12,000-ohm relay R is energized, and a local circuit for the calling lamp C.L. is completed. The B operator pushes over the speaking-

The junction line has thus been automatically disconnected at both ends instantly and is available for another call even although the plugs have not been withdrawn. The onus of determining disconnection is on the calling subscriber, and should he fail to hang up his receiver the called subscriber calls the operator's attention to the irregularity when he hangs up his receiver by causing the supervisory lamp to glow. The caller, immediately he hangs up his receiver, re-associates his calling relay and lamp with his line and causes it to test idle, but does not release the called line. The called subscriber must replace his receiver to release his line and also the junction line.

It is believed that the fact of the supervisory lamps glowing during conversation will be a very valuable feature from the point of view of supervision, particularly in enabling a traffic supervisor to note at any period of the day the load of the position and the load of the junction lines. It is reasonable to expect also that the carrying

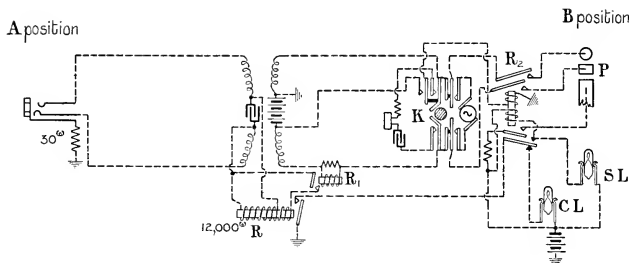

FIG. 4.

key lever to join up her telephone, and a local circuit is also completed through one winding of the cut-off relay R, so that it is energized to cut off the calling lamp C.L. and complete the retaining circuit previously mentioned. It also completes the circuit of all conductors through to the plug P. The supervisory lamp S.L. also glows. The operator tests and rings in the usual manner.

When the called subscriber answers the supervisory relay R₂ is energized and shunts the 12,000-ohm winding, so that the supervisory relay S (Fig. 1) at the A position shunts and puts out the associated lamp L, and the holding circuit of the cut-off relay D.D. at that position is completed.

When the called subscriber hangs up his receiver after a conversation, the B-position supervisory relay R₂ is energized, and the shunt removed from relay R, so that if the calling subscriber has replaced his receiver the A-position supervisory relay S and the cut-off relay D.D. are de-energized. All the conductors to the A-position plug C.P. are therefore opened, and the B-position relay R is de-energized. This opens the retaining circuit of the cut-off relay R, so that it is de-energized and opens all the conductors to the plug P, allowing the line relay and lamp to be re-associated with the called line and the line to test idle. The supervisory lamp S.L. ceases to glow and the calling lamp C.L. is re-associated with the junction line.

capacity of the junctions will be increased, as they cannot be delayed by slow releasing of the lines.

JUNCTION WORKING WITH THE B POSITIONS UNALTERED.

In certain circumstances it may not be considered advisable to alter the incoming ends of the junction lines on the B positions. This at any rate might be delayed without sacrificing a very great deal of the efficiency of the system. When two lines are joined together locally, i.e. in the same exchange, the full advantage would be obtained if the board were of the complete multiple type. If, however, it were worked on the transfer system, and in the case of connections through another exchange, all the advantages would be obtained with the exception of the automatic disconnection at the B position and the consequent instant release of the called subscriber's line. His line would test "busy" and the line lamp would not be re-associated with the line until the operator withdrew the plug as at present.

Owing to the high efficiency of the operating at these positions this might not amount to a great deal, and might not be noticed in service tests.

The junction would be automatically released when both subscribers replaced their receivers, and the clearing signal would be instantly given to the B operator. That

operator by the lamps glowing would know what lines were idle although she had not had time to remove the plugs and could again bring the lines into use by removing the plug from one part of the multiple to another.

The private branch exchange lines at each end of the circuit would both be instantly automatically disconnected, all the lines would be opened at the A position, and the clearing signal would be given at the B position.

When the connection was through two exchanges the loss would be somewhat greater, as the clearing in the second exchange would depend on the withdrawal of the plug at the first exchange.

SYSTEM USING DISCONNECTING KEYS.

For small multiple switchboards for public service, or as branch exchanges in subscribers' offices, the author prefers

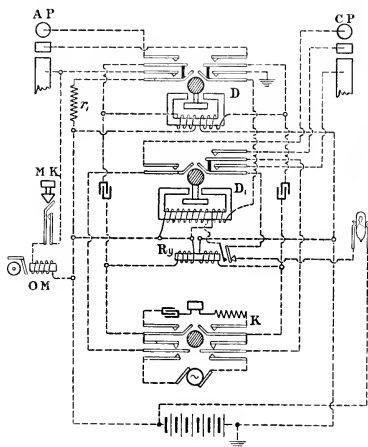

FIG. 5.

to use keys to take the place of the relays formerly described. Fig. 6 shows a combined speaking, ringing, and two disconnecting keys mounted on a common frame, the two latter keys being electromagnetically controlled. This arrangement is very compact. The "Stone" system of transmission is best adapted for use with electromagnetic keys as it is not then necessary to shunt them; preferably used with a 40-volt main battery. The circuit is shown in Fig. 5. When the operator presses over the speaking-key lever to join up her telephone, it engages with the two levers of the cut-off keys and forces them over also.

The coils of the keys are joined to the conductors by the springs, the inner ends of the coil D being connected to the battery. As the caller's microphone is then in circuit

current flows through the coil of the answering-cord key so that it is retained after the speaking key is moved to another position. The springs of this key also complete a circuit of one winding of the key in the calling circuit, so that it also is retained and connects the conductors through to the calling plug. A double-wound relay is connected across the loop with the inner ends connected to the battery, and current is supplied through this to the called subscriber's microphone. The supervisory lamp circuit is completed by the back contact, and the holding circuit of the cut-off key by the front contact. The former enables the called subscriber to signal the operator should the caller fail to replace the receiver promptly after conversation.

When the caller replaces his receiver the cut-off key D is de-energized and opens the conductors, so that his line

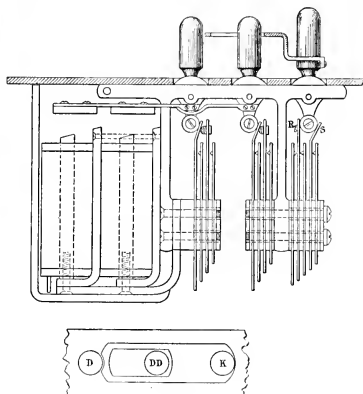

FIG. 6.

tests idle, and a second call can be sent in instantly. The energizing coil of the calling cord key is also opened, but it is still held operated by current over the line, maintaining relay R, energized, and only when the called subscriber restores his receiver does relay R, and key D' become de-energized and open all conductors to the plug C P so that his line tests "idle" and his line lamp becomes re-associated with his line.

As the circuit is opened when the caller's receiver is replaced, and cannot be re-established without the intervention of the operator, the answering cord should then be reckoned as "idle," but the operator must wait until the second lever returns to normal before withdrawing the calling plug to avoid re-associating the called subscriber's calling lamp with the line until the receiver is replaced.

PRIVATE BRANCH EXCHANGES.

Automatic disconnection is particularly applicable to this type of installation of the non-multiple kind in subscribers'

offices. It is essential, however, in order to obtain all the advantages described, to use line and cut-off relays instead of a line relay with a break jack as is usual.

With a view to reducing the cost and saving space, combined or twin relays should be used. These are common in automatic practice, but have not hitherto been used in manual systems. A common core is used with a central ring, which with the armatures and magnetic returns complete two independent magnetic circuits. Fig. 7 shows a suitable design.

The cord circuit is illustrated in Fig. 8. The keys are shown separated in order to simplify the diagram. The electromagnetic key D takes the place of the answering cord supervisory signal and the bridging coil through which current is fed. There are no condensers in the

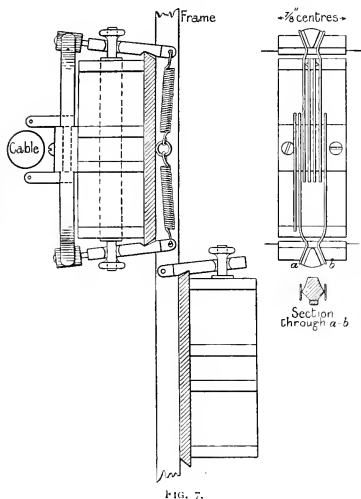

FIG. 7.

conductors, and the double winding of the cut-off key is connected across the loop when the key is operated, with the inner ends connected to the relay R_1 contacts. When relay R_1 is not energized another coil B is in series with the windings to complete the circuit, but when the relay is energized the windings are connected to a local battery or feeder mains to supply current for a local connection. The supervisory signal is replaced by a relay R which shunts the lamp L and also controls the slow-acting relay R_2 so that the local line connected to the answering or calling cord can disconnect the circuits. Relay R_2 is a retaining relay which is energized when the bridge is completed across the loop by the lever being pressed over and the momentary contact x completed. Relay R_3 thus keeps the circuit completed when the operator moves

the key K to the ringing position, until the called subscriber answers. Relay R_1 then short-circuits R_2 so that it is de-energized, and thereby relay R controls the connection and opens the circuit at the termination of the conversation. Relay R_1 is slow to release to allow R to pulsate the lamp L when the switch-hook is moved to call the operator. This allows calls to be transferred from one station to another.

The line circuits on the jacks are somewhat modified. Each exchange line has two jacks, the upper or answering jack having the bush insulated, while the lower or calling jack has the bush connected through an 80-ohm resistance to earth. The line indicator with a condenser in series is permanently connected across the exchange line. The cut-off relay coils on the local lines are of high resistance

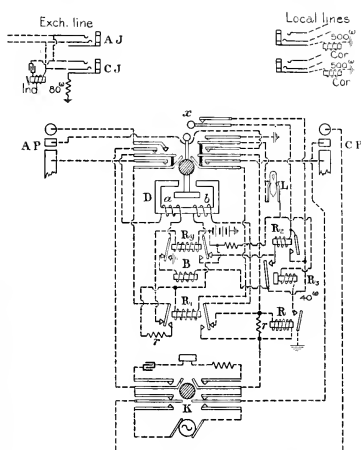

FIG. 8.

—say 500 ohms. In the cord circuit the calling plug has the third conductor connected through a low-resistance relay R' to the battery and earth. When energized, this relay by one set of contacts opens the circuit of relay R_1 and connects the sleeve of the plug AP through the resistance r to the battery and earth, so that the cut-off relay of the extension line may be energized. Relay R_1 by another set of contacts switches the battery through one winding of the coil of the cut-off key D from one side of the supervisory relay R to the other, so that relay R is always associated with the local line.

When a call is received from the exchange the plug AP is inserted in the upper jack AJ, and, as the bush of that jack is insulated, relay R_1 is not energized when the levers of keys K and D are pressed over. A circuit is then completed from the main exchange battery through the cut-off key winding DD in the calling cord there, over the line

circuit, through the windings of key D at the private branch exchange, through coil B, and the winding of relay R, the circuit having been momentarily closed by the contact x of key D which caused relay R, to be energized and be retained. The holding circuit of DD is thus completed at the main exchange, and the supervisory lamp shunted out, and at the private branch exchange the cut-off key D and relay R₁ are energized, and they remain in that condition after the key K is moved to the ringing position. When the plug CP is inserted in the jack of the line wanted the cut-off relay is energized, but the relay R₁ is biased against this current.

When the called subscriber answers, a circuit is completed through relay R, which shunts out the lamp L by the 40-ohm winding of relay R, that is also energized, and it short-circuits the winding of R, so that it is de-energized, and relay R₁ completes the circuit for the bridge across the loop.

When the called subscriber replaces the receiver, relay R, through relay R₁, opens the bridge circuit so that key D is restored to its normal position, indicating to the private branch exchange operator that the cords are available for further use. Key D in turn opens the line circuits and de-energizes the key DD at the central exchange. The exchange line has thus been instantly cleared at both ends and made available for another connection in either direction.

When a call originates with a private branch exchange line the plug AP is used for answering, and the key is thrown over, a circuit then being completed through relay R₂ and the cut-off relay COR. Relay R₂ connects the battery between the two windings of the key D so that the caller can talk to the operator. If connection is wanted with the exchange the plug CP is inserted in the lower or calling jack CJ. A circuit is then completed through the 80-ohm spool on the jack bush, through relay R₁, and the latter relay cuts the circuit of R₂ so

that it is de-energized and replaces the local battery by the coil B, as current for the microphone on an exchange connection is to be fed from the central battery. Relay R₂ also connects the winding of the coil D to the plug CP side of relay R, so that the latter is associated with the circuit of plug AP. The exchange is called automatically, as the coil B completes the loop circuit. The springs of relay R, should be so adjusted that they make contact before breaking, so that the key D may not release. Relay R₂ will energize, and will in turn be cut out of circuit when the relay R₁ is energized. The calling line cut-off relay will be kept in operation by current through the resistance r. At the central exchange the answering cord key D will be maintained energized over the caller's line and microphone. When the caller's receiver is replaced, relay R₁ will be de-energized and by relay R₂ open the circuit of coils B and D, so that the key D at the central exchange and the key D at the private branch exchange will be simultaneously de-energized, and the line will be instantly cleared at both ends.

Should a local connection be contemplated the plug AP will be inserted in the caller's jack and relay R₂ will be energized, so that current will be provided for the calling line; and when the plug CP is inserted in the called line jack, relay R₁ will not be energized, so that current will be available to energize both microphones. In such a case the circuit will be automatically disconnected only when the receivers at both stations are replaced.

It is thought that a single cut-off key will not be objectionable on these small boards, because there would always be a plug over a lamp which might glow if the called subscriber kept his receiver in his hand after the caller had replaced his receiver.

Suitable circuits are also provided for giving automatic disconnection on extension line switches and on cordless switchboards.

DISCUSSION ON

"THE EMPLOYMENT OF POWER IN H.M. POST OFFICE."*

SCOTTISH LOCAL SECTION, 13TH JANUARY, 1914.

Mr. W. W. LACKIE: The use of electrical energy in the Post Office can never be dissociated from the name of the late Sir William Preece, who preached and practised the doctrine that electricity is the poor man's light so successfully that electric light was adopted in the principal post offices throughout the country; he thereby was of considerable assistance to the electrical industry when such assistance was much needed. It is evident from Mr. Guntton's paper that electricity in the Post Office has passed through the same cycle of development that it has done elsewhere. That is to say, they began by adopting electricity for lighting, and then proceeded to use it for power, until now the power load is greater than the lighting load. It may be of interest to mention that 22 years ago the Post Office in George-square, Glasgow, was supplied with electricity by a private company who had a power station in a basement, two storeys below the street level in Miller-street. There were three arc-lighting machines, each machine being capable of lighting three arc lamps; and the two plants comprised two 75-h.p. engines with generators and these three arc-lighting machines, one of which is now housed in the entrance hall of Port Dundas electricity works under a glass case. When the Corporation took over the electricity supply in Glasgow the Post Office authorities installed plant of their own in George-square, but in the near future they are to take the whole of their supply from the Corporation.

The curves given by Mr. Guntton for hydraulic and electric lifts are most interesting and will be very useful. They remove all doubt as to whether an electric or a hydraulic hoist is best for an ordinary office, as the number of journeys in such cases is certainly 100,000 per annum. If any criticism could be made on this paper it would be in regard to the General Post Office's erecting a comparatively small private generating station in London. I would also suggest to the author that he should further investigate the cost of electric cooking.

Mr. A. PAGE: There is one point which specially interests me in connection with the paper, namely, the relays that protect the supply in the event of a failure of the power-station plant. I should like to know if before this system becomes properly operative the sub-stations are shut down and are started from the battery; because if they are not, and we assume them to be running upon practically the full load, the battery must be a very large one indeed before it can take up a load of 1,250 kw. Our experience at Glasgow is that discriminating relays are not to be depended on, and we are tending to do away with them instead of extending their use. Another point is how is the power station restarted in the event of the battery's carrying the sub-station load? Is the synchronizing done at the power station or sub-station end of the feeders, and how is it effected? Has the earthing of the star-point in the case of a pressure of 6,500 volts proved satisfactory? We do not think that it is necessary to earth here, as we generally

manage to keep running when we have an earth on one side; that, of course, presupposes that the insulation on the other two phases is very good. I wish we could get in Glasgow an average rate of 1½d. for a supply of power and lighting with such a good load factor. The daily load factor is given as 70 per cent and the weekly load factor as 50 or 59 per cent. It would be interesting to hear what the yearly load factor is, as that is the factor which counts.

Reference is made to belt-driven air compressors as against a direct drive, and the author says that in smaller installations belt-driven sets are employed because they are more efficient and economical. A little more explanation on that point might be given. We are told that gas is sometimes drawn into the street tubes run on the suction or vacuum system. Unless special arrangements are made that must cause a great deal of trouble. I should like to know how this gas is in the first place detected and then got rid of. We are unfortunately occasionally called upon to find out the position of faults in electric cables, but a blocked pneumatic tube must be a worse problem and present considerable difficulties in ascertaining where the carriers are fixed and how they are to be got at. It must presumably mean opening up the ground. The curves in connection with lifts may prevent our recommending the electric drive in the future when it is wrong to do so and when we might well leave the field to the hydraulic engineer. I do not think there will be many cases of that kind, but it is well to know the pitfalls of which we have got to keep clear. A single unsatisfactory installation leads to a good deal of talking, and that must be avoided. In conclusion, Scottish members would have liked the author to refer to "British firms" instead of to "English firms."

Mr. G. STEVENSON: I should like to ask the author why he adopted different types of converting machinery in the various sub-stations. I notice that in the Blackfriars station there is a 35-kw. synchronous motor-generator, and in the G.P.O. west sub-stations motor-converter sets. I should be glad if the author would state in his reply the reason for adopting synchronous motor-generators. I suppose it is for the purpose of improving the power factor. In regard to the 440-volt three-phase power supply, I should like to know what proportion of the load consists of induction motors; as far as I could make out from the diagrams in the paper the greater part of the load consists of lighting. I take it that at any rate the compressor plant would be driven by induction motors; if that is so, the total load would be somewhere in the neighbourhood of 900 h.p.

Mr. A. P. ROBERTSON: I noticed particularly one point with regard to electric traction. I take it that the testing track for the battery trucks is level and that the trucks have only at the present time to be used on subways. It seems to me a curious way to test a loaded vehicle upon a level surface without taking account of hills and rough road surface. When ascending a hill the vehicle takes

* Paper by Mr. H. C. Guntton (see pp. 100 and 202).

Mr. Robertson. much more current than might perhaps be expected on first consideration, and for general road traffic it is bound to take still more when it has to run on all sorts of roads. I should like to know if the truck system is intended for use on the streets or only indoors for Post Office traffic, or on subways from post offices adjacent to railway stations.

Mr. Guntton. Mr. H. C. GUNTON (*in reply*): Mr. Lackie has naturally referred to the question of our supply of electrical energy, and I should like to make it perfectly clear that the 1½d. per unit to which reference has been made is the cost per unit delivered for lighting and power in London. We have had to wait some time to justify the shutting down of our station in Glasgow, the reason being that we have used our exhaust steam for heating purposes; but we are now in a position to take a supply with economy and in a convenient and safe form from the Glasgow Corporation mains.

With regard to the points raised by Mr. Page, the transference of the load to the battery is quite automatic. The continuous-current busbar relay, on reversal taking place, causes the boosters to be automatically shut down and short-circuited; this is desirable, as their voltage might at the time be opposing the voltage of the battery. The pneumatic load and the power load at King Edward Building would also be removed automatically if the conditions of the load and the state of the battery at the time were such that it would not have been safe to leave these tripping circuits inoperative and so attempt to maintain the power load as well as the lighting. The next step would be for the shift engineer to open the booster tripping circuit, start up the boosters again, and add their voltage to that of the battery in order to keep up the pressure of supply and facilitate synchronizing again with the power station. He would then communicate with the power station, and if the trouble was not likely to be of long duration he could open the remaining tripping

circuits and so enable the power motors to be started up again. This arrangement has been called upon to act in the manner described, and has never, so far, failed us as regards maintaining the lighting supply. We have never had any difficulty in synchronizing and switching in with the power station. The question as to whether an earthed or unearthed neutral is the best is one which has often been discussed and upon which opinion has always been divided.

The advantage of the belt-driven compressor is that a high-speed electric motor can be used with a low-speed compressor, which we have found to give very satisfactory running results. So far as dealing with gas leaks is concerned, we test for gas periodically, and when it is found we depart temporarily from the "pumping through" system and deliver from the vacuum pump into the atmosphere instead of compressing up to the operating pressure. We have in addition fitted anti-explosion doors and duplicate mains so as to be able to keep the latter quite free from oily deposits likely to give rise to spontaneous combustion. I am glad Mr. Page has drawn my attention to the expression "English firms." The reference should certainly have been to "British firms."

Replying to Mr. Stevenson with regard to the two different types of transforming machinery in the sub-stations, continuous current was necessary in any case for battery charging, and was preferable for driving the pneumatic pumps. It was decided to combine as far as possible, by means of a composite system, the advantages of both the alternating and continuous-current systems of supply. The continuous-current plant, which requires constant attention, is concentrated at one of the three sub-stations and is operated in such a manner as to maintain the power factor of the whole system at a high figure without seriously lowering the overall efficiency, while the battery provides a valuable factor of reliability in connection with the supply from all three sub-stations.

WESTERN LOCAL SECTION, 10TH JANUARY, 1914.

Mr. F. TREMAIN: As regards conveyers, I have calculated that the one installed at the Bristol head post office could handle if necessary 500 tons per day. In connection with the "general lighting" of large rooms, I do not think we have yet got a perfect system, as in the instrument room at Bristol some of the officers recently experienced difficulty due to the shadows cast by their own bodies. The lamps have, however, been re-arranged to overcome this difficulty. The ideal system for a telegraph instrument room is indirect lighting, and I hope that with the advent of the ½-watt lamp such rooms will be illuminated in this way. The desirability of white walls and ceilings is beginning to be realized and will no doubt contribute to a perfectly satisfactory illumination of rooms of this kind. Where plant has been installed on a power basis for lighting a large office, it would be interesting to know the ampere-hour capacity of the battery, its relation to the number of kilowatts installed for lighting, and the length of time that such a battery would efficiently run the whole of the lamps without recharging. A battery which would provide the supply for the whole of the week-end in a big post office would be exceedingly large,

and I should like to know if such a battery has really been installed at the General Post Office, London.

It may be of interest to mention the lighting and power requirements of the Bristol Post Office and to consider the effect on the load factor of the supply station. The lighting installation is equivalent to 60 kw., and power to 55 kw. It is a lighting load which unfortunately comes on at the peak of the load, being coincident with that due to the residential and other demands. It would be to the mutual advantage of the Post Office and supply authorities if batteries were more generally installed in post offices for this purpose and the whole of the energy taken from the public supply between, say, 11 o'clock at night and 8 o'clock in the morning, as well as during certain hours in the daytime, energy for lighting being taken from the battery at other times. I raised the same question about eight years ago at Newcastle, but the subject was not then ripe for discussion. It would be interesting to know what should be the ampere-hour capacity of the battery in relation to the total kilowatt capacity of an installation for this purpose. At Bristol last year 74,000 units were used for lighting (that is, 1,200 per kilowatt installed) and 40,000

Mr. Tremain.

Mr. Tremain.

units for power (about 700 per kilowatt installed); the average cost was nearly 3d. per unit. If comparatively small stations can generate energy at 1½d. per unit as has been stated, including capital charges and depreciation, the Post Office has a strong case for better terms from the public supply authorities. We know that small country-house stations can generate energy at less than 1d. per unit. I suggest that the Post Office should take current from the public supply authorities in large towns at the most convenient period when the generating plant is nearly idle, and arrange terms to their mutual advantage, thus avoiding the necessity of increasing the size of the mains, etc., to provide for the ever-growing peak load due to lighting and cooking. In the South-Western engineering district there are some 20 towns where a supply of electrical energy is taken for lighting and power in post offices from the public supply authority. I should like to see every post office lighted by electricity, and where the supply cannot be obtained from this source, I would suggest the installation of small "country-house" generating sets.

Mr. W. A. CHAMEN: There are quite a number of small towns in which the electricity supply companies are in a position to supply electrical energy to the local post offices in the same way that the municipalities do in the case of large towns. I am surprised that the Post Office is constructing an underground railway of its own, in view of the large number of underground railways that already exist in London.

Mr. J. W. SHERGOLD: I was specially interested in seeing the electrically-driven Silvertown truck. It collected parcel baskets from the various floors of the Post Office building, passed up and down all gradients, reached the street with ease, and finally arrived at the platform at Temple Meads station needing only one man to control it. The running of motor vans from large centres to and through outlying districts has resulted in a considerable saving to the department.

Mr. A. T. KINSEY: I should like to know what is the charge per unit for power at Birmingham and other places where post office generating stations have been shut down. I was pleased to see the diagram of the new sluice in connection with pneumatic tubes. It has hitherto been difficult to find a sluice which would hold the air, and if the new apparatus referred to proves satisfactory a considerable advance will have been made.

Mr. E. A. PINK: My experience of the Silvertown truck has been very satisfactory, and the truck has had severe tests. I should like to mention specially the great ease with which it can be controlled and the speed adjusted from 2 to 6 miles per hour as desired.

Mr. H. C. GUNTON (*in reply*): From Mr. Tremain's remarks there appears to be some misunderstanding with regard to the length of the King Edward Building conveyor, which is about 400 feet long. Up to this distance a continuous conveyor is the most suitable contrivance if room can be found for it. As regards general lighting of instrument rooms, no doubt in various offices it has been necessary to adjust or depart in detail from the systems referred to, in order to obtain satisfactory results and meet local requirements. Indirect lighting would be very effective, but it is doubtful whether the Post Office authorities would feel justified in going to the expense of providing it in sorting and instrument rooms. The Post Office has installed batteries in order to get the most favourable terms from the local suppliers of electricity (not necessary municipal) by raising the load factor, a stand-by being obtained at the same time. With regard to the capacity of the battery required to deal with the load in an emergency, the Birmingham battery has a capacity of 750 ampere-hours, and that in London 2,000 ampere-hours. This is sufficient to keep the power and lighting going for half an hour, and lighting alone for several hours. The manner in which the battery maintains the supply has been described in my reply to the discussion on this paper at Glasgow.² It is very satisfactory to have been able to obtain a British-made battery truck. The Edison battery has certainly taken a long time to develop, and it has been employed in this case principally because there was good ground for thinking that it could be used more roughly. The Silvertown truck has proved very satisfactory so far, but it is necessary that it should receive a more lengthy trial.

As regards the Post Office Railway there is plenty of room at the depth at which the Post Office work—the tunnelling is principally in clay, so that it is not necessary to use compressed air, and it is quite possible to work close to other people's property without doing any damage.

Where there is a complaint as to the lighting, a lumeter should be obtained and the amount of light measured at the point where it is being used.

In reply to Mr. Kinsey, it is as a rule necessary to obtain a price below 1d. per unit from public supply authorities before the Post Office is justified in shutting down its own plant, as the exhaust steam is used as a by-product. As the Post Office has to install separate heating plant when an outside supply is taken, it is necessary to consider the total cost of the installation, including heating, under the new and old conditions before making any change. With regard to ventilation, it is usual to use the extractor type of fan in conjunction with radiators.

² See page 330.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 22ND JANUARY, 1914.

Proceedings of the 561st Ordinary Meeting of The Institution of Electrical Engineers, held on Thursday, 22nd January, 1914—Mr. W. DUBDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 8th January, 1914, were taken as read, and confirmed.

Messrs. B. B. Heaviside and R. Grigg were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows :—

ELECTIONS.

Members.

Fortescue, Cecil Lewis.
Kennedy, John McFarlane.

Associate Members.

Evans, Llewelyn, Capt., R.E.
Fogarty, Laurence Francis.
Gillitt, Leonard.
Stamatopoulos, Andrew George.
Tanner, George Frederick.

Graduates.

Paliwa, Sundar Dass, B.Sc.

Walker, Ernest.
Wilson-Jones, Richard.

Students.

Bailey, Alan John.
Boscolo, Gioachino Ricardo.
Bromley, James Treasure.
Burleigh, Robert.
Eastman, Hugh.
Ethelston, Simon.
Giller, William Leslie.
Halford, William Charles John.
Hedgecock, Archibald David.

James, Malcolm Reginald.
Johnston, Ernest Chiford.
Killingback, Stanley Gordon.
Maidment, Roland Frederick J.
Mould, James.
Nath, Pandit Ragho.
Norman, Archibald Cuthbert.
Organ, Harold Percy.
Pendlebury, Stanley.
Rashid, Mohamed Abbas.
Vick, Ernest Henry.
Wilcock, Eric John.
Wong, Sid Lam.

TRANSFERS.

Associate Member to Member.
Coombs, Allen Murray.

Student to Associate Member.
Connan, John Cranmer.

Hills, Stanley Monceur.
Howarth, Oliver.
Page, George Wood Pearce.
Phillips, Thomas Francis.
Rennie, John Cameron.

Snowball, Bartholomew.

Student to Graduate.
Grant, Edgar George.
Spary, Percy George.

Donations to the *Library* were announced as having been received from The American Institute of Electrical Engineers, P. Boucherot, H. H. Broughton, The Canadian Department of Mines, Messrs. Constable & Co., Ltd., V. A. Cornelius, J. Eck, A. P. M. Fleming, The Institution of Civil Engineers, R. D. Lillibridge, La Lumière Electrique, M. Maclean, D.Sc., A. J. Stubbs, The United States Department of Commerce, R. M. Walmsley, D.Sc., L. H. Walter, and W. T. Wardale; and to the *Museum* from K. Hedges and The Norwegian Telegraphs Department, to whom the thanks of the meeting were duly accorded.

Sir Oliver Lodge, D.Sc., F.R.S., then delivered the Fifth Kelvin Lecture, entitled "The Electrification of the Atmosphere."

A vote of thanks to the lecturer was proposed by Dr. R. T. Glazebrook, C.B., F.R.S., and seconded by Professor Sylvanus P. Thompson, D.Sc., F.R.S., and the resolution was carried with acclamation. The meeting adjourned at 9.45 p.m.

THE FIFTH KELVIN LECTURE.

THE ELECTRIFICATION OF THE ATMOSPHERE, NATURAL AND ARTIFICIAL.

By SIR OLIVER LODGE, D.Sc., F.R.S., Member.

(Delivered 22nd January, 1914.)

When the President asked me to give the Kelvin Lecture he told me that it had no necessary connection with Lord Kelvin: he practically said, I think, that I might if I liked keep clear of Lord Kelvin; but in dealing with any branch of physics I find that quite impossible. I have always found in lecturing to students on almost any of the larger groups of physical science that Lord Kelvin was at the bottom of them; and in this matter of atmospheric electricity he began, I think I am right in saying—Professor Silvanus Thompson knows much more about these historical matters than I do—but I think I am right in saying that he practically began the accurate measurement of atmospheric electricity, devising instruments for the purpose and carrying out a number of measurements.

For measuring an atmospheric potential one method used to be to put an earth-connected sphere up to the place required, then to insulate it, carry it indoors by an insulating handle, and determine its charge. The sphere in a place where the potential, we will say, was naturally high was kept at zero potential by being earth connected. That could only be by its possessing an opposite charge sufficient to neutralize the natural potential in its neighbourhood, and if that charge is measured we get a measure of the potential which is due to it on the sphere.

Lord Kelvin, however, preferred not to use an earth-connected body, but to employ an insulated body and to bring it to the potential of the place considered by making it grow and break bits of itself off. Thus taking, let us say, a sphere once more, and putting it in its place with an elongated conductor connecting it to an electrometer, it would have an opposite charge induced upon it, even though insulated; but if made capable of emitting a series of proof planes, that is of emitting parts of its surface containing this opposite charge, that opposite charge might be got rid of, and so it would be bound ultimately to acquire the potential of the place where it was. That is the method of the smoking match, and of the water dropper. In both cases they are conductors which grow

and break bits of themselves off; they throw off the oppositely charged bits, and thereby gradually acquire the right potential. To measure the potential of a conductor is as easy as possible; simply connect it to an electrometer of either insignificant or of known capacity. To measure the potential of an insulator is not so easy, because how is it going to be connected? Well, that is the method, the water-dropper method or the smoking-match method, or some mechanical device which is practically the same thing. For portable work, work in the field, the smoking match is the best, the smoking rod. For recording work in an observatory the water-dropping method is the best. Lord Kelvin it was who devised these methods, and Observatories still use a jet of water which gradually grows and breaks into drops at the place whose potential is required.

As this is a Kelvin Lecture, I should like to throw on the screen some portraits of Lord Kelvin in different stages: first in the stage in which everyone in this room was familiar with him. Next I will show him in the stage when he had achieved his great work on the Atlantic cable, the stage soon after which I was privileged first to know him, a portrait which was given me by Lady Kelvin with the remark that she considered it the best that had been taken. Some in this room knew him then, but many did not at that age. Then there is the previous stage in which I expect nobody in this room knew him, Professor William Thomson of Glasgow, while he was engaged upon his, I was going to say, superhuman work in the highest parts of mathematical physics, in the forties and fifties of last century, before the fascinating problems of the Atlantic telegraph withdrew him to some extent from pure science into applied science, and made him three times President of this Institution.

It was at this earlier time that he began his atmospheric electrification experiments, and here is his portable electrometer with a tall rod terminating with a smoking match for measuring the potential of the atmosphere at the place

where the smoke particles are given off. That is the conductor which is growing and spitting away parts of itself in the form of smoke powder.

The portable electrometer employed in connection with this collector—I do not know that it is so much used nowadays—was one form of those attracted-disc electrometers which he devised and found most suitable for many purposes. For stationary positions his quadrant electrometer is of course more sensitive.

Here in Fig. 1 is a record of the meteorological observa-

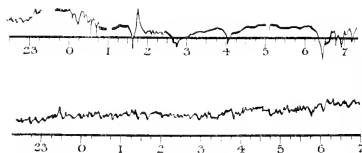

FIG. 1.—Results obtained by Self-recording Quadrant Electrometer with Water-dropping Collector.

tion of atmospheric electricity, I think at Kew, on two different days, made by a quadrant electrometer attached to a water-dropping collector. The lower diagram shows the positive potential of the higher air on a fine day, under fine weather conditions, a very steady positive potential. The upper diagram represents the conditions on a wet day. The potential has to struggle down to negative against the normal potential, for the upper air is normally positive. The earth is negatively charged; the levels above are positively charged. One is a cause of the other no doubt; there may be a question as to which is which. I myself think that the upper layers being positively charged is the chief cause of the negative electrification of the earth's surface, though there is always a possibility that any given planet is itself negatively charged as a whole. But I am inclined to think that it is more likely that the earth is one of the coats of a compact Leyden jar, with the upper atmosphere as the other coat; and that the lines of force from the earth do not to any great extent penetrate into the regions of space, or terminate—for they must terminate somewhere—on either the sun or some other planet.

The electric gradient in the atmosphere is normally positive downwards, but there may be a reversal in bad weather, a reversal before rain. We also sometimes get the reverse effect of dust and mist; before a dust cloud or before any wind containing solid or liquid particles we may get a reversal of the normal atmospheric charge. I suppose that that is due to something like friction, the generation of frictional electricity. But I have an open mind on nearly all these problems connected with atmospheric electricity because there are people now who study them more closely than I have been able to. Dr. Chree and Dr. Glazebrook, for instance, and others no doubt who are connected with Observatories, who have more recent knowledge of these matters; and theories must be given by those who are specially working on these lines.

I should like to read some of the early statements by Lord Kelvin on this subject. In the year 1856 he writes from Creuznach to his brother: "I have become acquainted

with a Mr. Dellmann here, who makes electrical observations for the Prussian Government. I have seen his mode of observation of atmospheric electricity which is very simple. There is always an effect of one kind indicating negative electrification of the earth's surface, but when the sky is much overcast there is little or none"; and that becomes important later on. There is this gradient of potential on a fine day, but on a cloudy day much less—"little or none" he says. "Detached clouds alter the effect quickly, sometimes give a great amount of reverse effect, and the first drops of a shower generally do so. I am having an electrometer of Mr. Dellmann's construction made." "The earth's surface is always found negative"—that is after he had made a lot of experiments—"day and night after fair weather, and only occasionally positive in broken weather or during an actual fall of rain in the immediate neighbourhood." Later on he speaks of observing many times, from May till September, 1859, with his portable electrometer in the Isle of Arran at Brodick Bay. "In ordinary fair weather I found the difference of potential between the earth and an insulated burning match at a height of 9 ft. above it to vary from 200 to 400 Daniell cells, or, as we now say, volts."

(It is rather interesting, this introduction of the familiar term "volts." It is interesting to me to know that in my lifetime ohms and volts and amperes took their birth. So did the whole C.G.S. system of measurement. We are all now so familiar with these units that it is difficult to believe they are not mentioned in the Book of Genesis; but they are comparatively recent innovations. I remember a very long time ago that as a unit of resistance we used to employ 70 ft. of No. 16 common bell wire. That was specified as somewhere about an ohm. The term "ohm" was certainly used before the others, but it was extremely difficult at that time to get into the heads of students, including myself, the way in which an ohm was really defined and measured, in absolute measure; especially as Lord Kelvin insisted, to my mind quite wrongly, that a resistance was really a velocity. My recollection is clear that the ohm came first, a long time first, and was defined as an earth-quadrant per second, or 10^9 C.G.S. units of velocity. It is really μ times a velocity. It is handy to remember that μ times the velocity of light is 30 ohms. That is an accurate statement of fact, except in so far as refined measurement may affect decimal places in the number 30, which cannot possibly be exactly 30 but must be incommensurable. The volt came next, and was defined so as to be of the same order of magnitude as the Daniell cell, which had been previously employed as the unit. Accordingly it became $1/300$ th of an electrostatic unit, or 10^8 C.G.S. magnetic units. The ampere naturally followed; with the inconvenience that it had to be one-tenth of a C.G.S. unit instead of a whole unit. Then came the watt, bringing us back to straightforward mechanics, without any unknown or etherial constants, and being equal to 10 million C.G.S. units of energy per second.)

Lord Kelvin usually found a potential of 200 or 400 volts for a 9-ft. elevation. Sometimes it rose to 3,000 or 4,000 volts with an east wind. He says that in fair weather he never found the potential other than positive, and later on he says: "The common fair weather condition I am forced to conclude is due to a paramount influence of positive electricity in higher regions of the air."

Now, I have put the above sentence in italics because I want to emphasize it as at any rate Lord Kelvin's opinion at that time. It is a moot point with me, and I believe with everybody, as to which is cause and which is effect in the changes of weather and the changes in sign of atmospheric electricity. It is certain that when the weather breaks up, the gradient changes and may be reversed in sign; but whether the break-up of the weather is the cause of the reversal of the potential, or vice versa, I do not know. Anyhow here Lord Kelvin considers that the fair-weather condition is due to positive electricity in the higher regions of the air, notwithstanding the negative electrification of air in the lower stratum near the earth's surface. Air close to the earth's surface is commonly negative. If a window of a room is opened and air allowed to come in, it will commonly be found to be negatively electrified. That is natural enough, because it has been receiving some electricity from points and edges on the negatively charged earth.

At a lecture at the Royal Institution in 1860 Lord Kelvin says: "If when the rain has ceased strong positive electricity obtains, it is a sign that the weather will continue fair for several days. If the electricity is but small, it is a sign that such weather will not last so much as that whole day, and that it will soon be cloudy again, or even will again rain."

With regard to the "electricity of clearing weather," if the clear weather is due to the electricity, as I venture to say I hope it is—it is very wrong to hope for things in science, I know, but I have a kind of hope that that is the case, and it will be seen why—we may imagine that we can acquire some control over the electrification of the atmosphere, and thereby and to that extent there would seem to be a feasible method of beginning a control of the weather—at least if the one is due to the other in the way that is here suggested.

There used to be some incredulity as to whether air or gases could really be electrified. It used to be thought—indeed I have heard Lord Kelvin himself say sometimes rather tentatively—that when we apparently electrify air, as for instance from a point, we were really only electrifying the dust—either dust given off from the point, or dust already in the air, of which there is always plenty. He doubted at that time—at any rate for a short time—whether atoms themselves could be electrified. He ultimately satisfied himself that they could, by an argument which Professor Elihu Thomson also used, to this effect: Imagine a charged sphere of water, a charged raindrop, for instance; let that raindrop evaporate; the evaporation carries off no charge. That has been completely proved, that the evaporation of vapour from a charged surface does not carry off any of the charge; the molecules that go away from the surface do not act as proof-planes. Evaporation then leaves the charge what it was, but the globe is getting smaller and smaller, till it disappears; and when it has gone the charge must remain in the vapour or in the air.

That was the argument. But the argument is not conclusive; for, as we know, Mr. Aitken of Edinburgh showed that there was a nucleus of dust necessary for the condensation of aqueous vapour. There would therefore be a dust nucleus, though a very minute, perhaps an ultra-microscopic one, at the centre of every

raindrop; and that little dust particle, it might be, which went off with the charge. Hence I say I do not think that argument fully substantiates the true electrification of an atom. But now, owing to the researches of Mr. C. T. R. Wilson and others, we know that there are other nuclei than dust particles which act as centres of condensation for water vapour; we know that nuclei can be called into existence by Röntgen rays, uranium rays, and ultra-violet light; that positive and negative ions differ only in their power of condensing water vapour, and that a cloud may form round either, though it forms more easily round the negative kind. And Sir J. J. Thomson has pointed out² that in consequence of this difference, when cloud particles fall under gravity electrical separation may take place. It is found by Wilson that there really is such a difference, the negative ions condensing water at a less super-saturation than positive ions require, and so tending to be carried downward and separated from the positive.

Again, there is the effect of light on electrified surfaces. Ultra-violet light falling upon a charged clean zinc surface, and indeed upon many another kind of surface, enables it to give off negative electricity freely. It emits electrons. I suppose, under the stimulus of the light waves; in fact, there is no question that it does. The discharge of electricity under the action of ultra-violet light is well known. I have found that leaves of trees and leaves of plants are very efficient givers-off of a charge under the action of ultra-violet light. (I made a lot of experiments of this kind while I was at Liverpool, and have the record of them, but it was never published.) Now, inasmuch as the surface of the earth is charged negatively, and inasmuch as it is exposed to ultra-violet light from the sun, it is manifest that the layer of atmosphere near the earth will get negatively charged. The lower air must be more or less negatively electrified with the same kind of electricity as that of the earth's surface, and since the tension reaches a high degree of intensity at every tree-top and pointed vegetable fibre, it must always cause more or less the phenomenon which becomes conspicuous as St. Elmo's fire. Hence in fair weather the lower air must be negative, although the atmospheric potential even close to the earth's surface is still generally positive. But a considerable area of this lower negatively-electrified stratum is carried up over any locality by wind blowing inwards from different directions; its effect may for a time predominate and give rise to a negative potential in the air and a positive electrification of the earth's surface. Moreover, and still more if it is churned up by a horizontal cyclone, the upper positive stratum and the lower negative stratum may get mixed to some extent with each other, and we may obtain the conditions for a discharge from the negative into the positive, that is, the conditions for a thunderstorm. I cannot but think that one cause of atmospheric electricity of the violent kind is due first to the influence of ultra-violet light in coaxing away some of the earth's negative charge into the air, and secondly to the wind, the revolving wind which accompanies or is associated with a thunderstorm, often a horizontal cyclone, churning these up, bringing them near one another, sufficiently near, within half a mile or so, for some flashes to take place.

It is almost a proverb that an English summer consists

² *Philosophical Magazine*, vol. 46 (Series 5), p. 528, 1898.

of two fine days and a thunderstorm, and although that is an exaggeration, yet one is familiar with the fact that after a good spell of sunshine we are very apt to find it finish off with a thunderstorm. I cannot but think that the two are connected, and I should imagine that over the sea or over the desert, where there must be less emission of negative electricity, the prevalence of thunderstorms would be less.

The next slide is intended really to show that the leaves of plants—a large number of different plants are here depicted—are by their shape well calculated to discharge electricity into the air. They are all pointed and serrated, some more than others, but on the whole one could not imagine a conductor of that kind holding its charge very well. It would appear as if they were intended to get rid of their electricity. And if that condition has been brought about by evolution it must be for some definite reason, presumably for the good of the plant. I want to emphasize that point, because if it is for the good of the plants that they should discharge electricity—that there should be a current up through the leaf—then it may be possible, by the artificial increase of the potential gradient above the earth, to increase this stimulus, to assist the electrical message or whatever is happening in the plant, to stimulate the natural processes by means of electrification. We must admit that from the shape of the leaves it is evidently suggested, on the principle of evolution, that such discharge of electricity is beneficial.

That sunlight assists this action is familiar, no doubt, and I will just remind members of a simple experiment. We have here an arc-light lantern with quartz lenses and a quartz prism (because glass is very opaque to ultra-violet light) arranged so that the spectrum can be seen. If we take a charged electroscope with a clean piece of zinc attached to it, and then move the piece of zinc until it is plunged into the invisible short-wave radiation, the maximum effect will be observed and the leaves collapse very rapidly, showing that under that stimulus the metals, like leaves, or indeed many surfaces—not all—get rid of their electricity, especially negative electricity, freely.

I have said that that action is probably associated with the production of thunderstorms, and although I am not dealing with the lightning aspect of atmospheric electricity to any great extent, yet I have some slides of lightning flashes, photographed by different people, which I will run quickly through the lantern, because some of them are rather striking and beautiful, though no doubt they are fairly familiar.

This flash shows the side flashes. It negatives the idea that a lightning flash is one definite thing and that if it strikes one place all other places are protected. A lightning conductor receives the main flash, but there are all these branch flashes which, though weaker than the main flash, are not by any means to be despised.

The next slide does not show a lightning flash, but an experiment—made by my assistant, Mr. Robinson, when we were investigating lightning—of sending a spark through rain. We had an artificial rain shower in the laboratory. We wanted to see how it was that it was possible to get such an enormous length of spark; and we found that through raindrops we could get a very great length of spark from an ordinary Voss machine. This represents a laboratory lightning flash assisted by artificial rain.

The next slide shows a real lightning flash tying itself up into knots in the most extraordinary way, and I presume doing so because it is dodging about from one rain-drop to the next. It does not care particularly which way it goes, but it takes any raindrop that it happens to find within range, whether such drop is in a straight line towards the earth, or to the cloud, or in any other way. Of course a good deal of that apparent return upon itself must be merely foreshortening; but still the irregular path is remarkable. It does not know that a straight line is the shortest distance between two points.

Here is a photograph taken by my assistant when he was attending a football match, because he saw there rather a remarkable occurrence, which I will venture to bring to the notice of this audience. A great metal roof supported by iron stanchions will be seen. There was a thunderstorm going on at the time and the building was not struck, but a youth was leaning against one of the metal posts. There must have been a charge in the roof area produced by induction, a static charge, which was liberated by some flash—"Lord Mahon's returning stroke," as Tyndall used to call it. The charged area then discharging down this pillar, and no doubt also down the others, gave the young fellow who was leaning against it a shock which precipitated him violently into the midst of the crowd in front, causing a sensation and making the people think he was killed. He was astonished and "shocked," but not damaged. I mention this case as one that came under skilled observation. It actually occurred at the time of a neighbouring flash. The metal conductor, against which the youth was leaning was no doubt earthed—one would expect it to be much better earthed than a man standing on a form and leaning against it could be; but it is only characteristic of what happens. These side flashes indicate how high the potential may be for these sudden rushes of electricity; they demonstrate that one cannot lean against lightning conductors with impunity. There have been distinguished Presidents of this Institution who have thought otherwise, but I do not think on experimental grounds.

Here are a number of multiple flashes showing a complete rot in the air. If it gives way at one point it gives way at a large number of points, because the air becomes conducting, as it does in a vacuum directly the discharge begins.

Next we have one of the regular stock pictures of the aurora borealis, showing that curious fringe or curtain effect, which I only show here for comparison with the next photograph, which shows the banded effect of a lightning flash. The appearance of that lightning flash, showing a broad ribbon-like band, is not due to movement of the camera. I assume it to be due to the blowing away of the aura from the main discharge. It is presumably going sideways down the wind, but is still sufficiently bright to leave an impression on the plate. Perhaps some of those present have a better theory of those effects, which do sometimes occur and which remind one of the curtain effect of the aurora. The dark part of a flash appears to be only a photographic effect, a well-known effect of over-exposure. But as regards the constitution of the aurora, which undoubtedly is a subject of electrical interest, it will be convenient to quote here for future reference a paragraph from an article by Dr. Fournier d'Albe in the *English Mechanic* for 19th May, 1911.

SPECTRUM OF THE AURORA.

"In 1906 Störmer published in a Swedish journal a paper 'On the Trajectories of Electric Corpuscles in Space under the Influence of Terrestrial Magnetism, applied to the Aurora Borealis and to Magnetic Disturbances.' He therein showed, by calculations and models, that the aurora is due to electrons projected by the sun and bent round upon the dark side of the earth by the earth's magnetic field. This has recently been confirmed by the stereoscopic photographs taken by Norwegian expeditions organized by Birkeland. The most striking thing about these electrons is their extraordinary speed, which differs by less than 1/10th of one per cent from the velocity of light itself.

"According to observations made in vacuum tubes, air becomes opaque to cathode rays when its pressure attains 0.1 mm. of mercury. This happens at a height of 37 miles. That, therefore, is the limit of auroral displays, and it is significant that the most reliable observations—those of 'draperies'—give that height as the inferior limit. The highest auroras are the steady, homogeneous arches, in which no waving or crenulating action is discernible. Paulsen and La Cour endeavoured to determine their elevation by theodolite, but found them too high for accurate measurement. They cannot have been lower than 250 or 300 miles.

"Now, it is well to remember that the radiating aurora owes its light mainly to nitrogen. The violet light is chiefly due to the line 391. The red light which sometimes shines out is composed of the lines 631 and 519, both of which belong to the anode spectrum of nitrogen. Of the hydrogen lines, the one at 486 is established beyond a doubt. Those at 656, 410, and 434 are more or less doubtful. The following comparison between the top and bottom of the same auroral structure is due to Carlheim-Gyllenskjöld. It distinctly shows the decrease of nitrogen and increase of hydrogen with increasing height:—

Spectrum	Number of Lines	
	Top	Bottom
Air spectrum	9	8
Nitrogen, anode spectrum...	2	4
Nitrogen, cathode spectrum	10	14
Hydrogen spectrum	3	1
Unknown	8	4

The helium line, 502, is suggested by the lines imperfectly observed at 500 and 505.

"The greatest controversy still rages about the chief auroral line, 557. This was observed most unmistakably by La Cour and Paulsen. This value differs considerably from that of the chief line of the solar coronium, whose position is 532.7. Nevertheless, this must not be taken as proving that coronium and the auroral gas are different, more especially as the corona owes its luminosity to temperature, whereas the aurora owes it to electric discharges. It is possible that an atmosphere of a gas provisionally called 'geo-coronium' is productive of the Zodiacal Light, and the observed irregularities of the latter are another point of analogy with the solar corona."

CAUSES OF THE EARTH'S ELECTRIFICATION.

Now I want to say a word about the causes of the earth's electrification, the causes of natural atmospheric electri-

city. I must be very brief on this point. Many suggestions have been made as to the splashing of water, the evaporation or condensation and falling of rain, and other effects of that kind, but I myself am in favour of a cosmic cause rather than a local cause. I think it must be largely or mainly due to particles coming from the sun. The sun is a charged body. We know by the investigations of sun-spots that there are crowds of electrons there causing a magnetic condition. We know it can produce magnetic storms on the earth when one of its ejected torrents of electrons comes anywhere near us. At any rate that is the way I think of it. And we know that a hot body gives off electricity—electric evaporation as Professor O. W. Richardson called it the other day in his Inaugural Lecture at King's College. The sun must give off alpha and beta rays; and when these come near the earth the beta rays, the electrons, the negatively charged bodies, are entangled as it were in the earth's lines of force and conducted to the poles, conducted on the whole spirally round the earth's lines of force into the Arctic and Antarctic regions, being easily deflected by a magnetic field.

The alpha particles, the positively charged bodies, are not so easily deflected. They are barely deflected at all, and therefore will come down with the sunshine mainly into the tropics. I take it therefore that the equatorial regions of the earth or the earth's atmosphere are liable to receive a good deal of the positive solar emission, and that the polar regions are liable to receive the electrons, which no doubt are responsible for most of the aurora; and then I suppose these charges re-unite as best they can, by earth currents or other ways, through the crust of the earth or through the atmosphere. That I think is what mainly accounts for the upper positive charge of the earth's atmosphere. Also the earth's atmosphere is ionized and rain brings down the negative electricity, leaving the positive up there. That is another cause.

But the ionization: What is that due to? Well, alpha rays ionize air, and gamma rays ionize air; gamma rays are very penetrating and may ionize the lower stratum, while the other rays would act usually in the upper regions. An ionized atmosphere conducts, hence there must be a downward current. If there is a positive gradient there must be a downward current, and the amount of that current can be estimated; roughly speaking, the ordinary fine weather gradient is one volt per centimetre. It may vary a good deal, but roughly that is the order of magnitude, one volt per centimetre. The downward current ordinarily is about one micro-ampere per square kilometre; an exceedingly small current, because of course the air is very nearly an insulator. The main effect in the atmosphere is the potential gradient; a very minor effect is the current which is continually flowing down.

In the upper layers the conductivity is of course far greater. Undoubtedly, rarefied air conducts, and it must be because it is ionized. There is a pressure at which the conductivity reaches a maximum; that pressure must exist in the upper atmosphere. Accordingly there must be a good conducting layer round the earth. If it consisted of electrons it would be opaque, but if it consists of electrolytic ions it need not be. We know that negative ions are slightly more mobile than positive ions in any

case, especially at reduced pressures, but their mobility is not of a different order of magnitude, as it would be if they were electrons.

Here is a diagram (Fig. 2) prepared by M. Langevin, showing the mobility of atmospheric ions, both positive

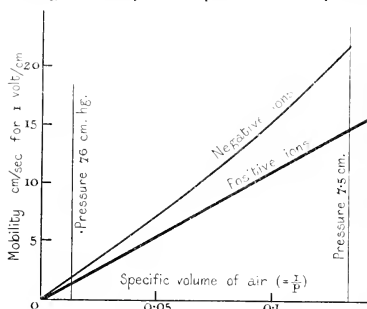

FIG. 2.—Mobility of Atmospheric Ions (Langevin).

and negative, at different pressures; and the conductivity of course depends on the mobility. The mobility was measured by him, under a gradient of a known number of volts per centimetre, by the device of driving them back by means of an air blast, and so neutralizing their motion, and measuring the speed of the blast necessary to check the current. The results are plotted not with regard to pressure, but with regard to inverse pressure, so as to show readily the inverse proportionality between pressure and mobility. Hence the conductivity, which depends on the mobility and the concentration together, seems to be fairly independent of the pressure for a given amount of ionization. But of course the ionization at different levels is not constant, and a great deal more has to be ascertained about the effective conductivity of the upper atmosphere.

But it may be said that conductors ought to be opaque, and if the air is a conductor how can it possibly be transparent? Well, this question of opacity is one which I have written on in the *Philosophical Magazine* not long ago (June, 1913). There are different kinds of opacity in the atmosphere, which are observed in connection with wireless telegraphy, and there are certain kinds of opacity which affect long waves but do not affect short waves. We are familiar with that kind of conductivity in liquids. A liquid screen could be fairly opaque—a thick screen of dilute sulphuric acid would be fairly opaque—to Hertz waves, but it is transparent to light. Electrolytes need not be opaque to the slight and excessively rapid quiverings which constitute light; these appear to be able to get through an electrolytic conductor without much waste. But with steady currents—and long waves of course approach steady currents rather more than rapid vibrations do—the conductivity becomes effective. The ionic carriers

in the case of electrolytes are comparatively heavy things, molecules or perhaps molecular aggregates. In metals the conveyer of electricity is the electron, and that is affected even by light waves, and so metals are opaque to every kind of wave.

But what about the atmosphere? Little is known about the upper atmosphere. It is remarkable how we live here and know so little about the atmosphere above our heads and about the ground beneath our feet. We explore the surface; we penetrate the crust to about a mile for commercial purposes; we penetrate the earth's atmosphere to about five miles or thereabouts—possibly now as much as nine miles. I think that further vertical exploration is wanted. We have nearly exhausted the surface of the earth now that the poles have been more or less conquered, but "up" and "down" seem to want further exploration. I expect that that will some day be undertaken. To quote Dr. Fournier d'Albe again:

"Already some progress has been made. It is now thought by many meteorologists that the earth is surrounded by successive shells of different physical and chemical constitution. The crust of the earth is no longer clothed in a gaseous envelope of uniform composition, merging insensibly and steadily into the interstellar ether. There are at least two atmospheric skins, and at the present rate of progress our resemblance to an onion will soon become quite obvious.

"The manner in which this change of views has been brought about is instructive. It began with the *ballons sondes*, small free balloons provided with registering apparatus, sent up by M. Teisserenc de Bort from his observatory at Trappes, near Paris, in 1901. He, and Assmann in Germany, shortly afterwards, found that after a certain height is passed—it ranges from 23,000 to 36,000 ft.—the thermometer ceases to fall on rising further into the air. It stands at -67° F., and stops there."

[Since the Lecture was delivered the following note has appeared in *Nature* for 12th February, 1914, page 666:—"Information has been received that through the generosity of Mrs. Rotch, the observatory at Blue Hill, near Boston, founded by the late Professor Lawrence Rotch, for the study of the upper air, and partially endowed by his bequest of fifty thousand dollars, has been established for five years in connection with Harvard College. Mr. McAdie, formerly in charge of the Californian section of the United States Weather Bureau, has been appointed director of the observatory, and at the same time professor of dynamical meteorology in Harvard University. We also understand that provision is to be made in connection with the French Department of War for continuing the aérolological

* SIR O. LODGE. "On a Dynamo for maintaining Electrical Vibrations of High Frequency, with Some Notes on the Transmission of Waves in Wireless Telegraphy." *Philosophical Magazine*, vol. 25 (Series 6), p. 757, 1913.

work carried on by the late M. Léon Teisserenc de Bort, at his observatory at Trappes."]

But it is not easy to explore the upper atmosphere. The best method hitherto has been kites. Kites carrying meteorological instruments have certainly been made to fly to considerable heights, and the French have, as said above, sent up their *ballons sondes* still further, and discovered the isothermal layer. But there is a handy method of exploring the atmosphere further, by means of Hertzian waves. It is familiar how in wireless telegraphy the distance to which Hertz waves penetrate is much greater than would have been expected. There is something that assists them round the curvature of the earth; I cannot but feel, and Dr. Eccles among others has worked out an ingenious theory, that the upper air contributes a good deal to this effect—the conductivity, the ionization of the upper air.

It is a fact that wireless waves curve part way round the earth; but what is the reason of their curving round? Waves should be sent up for the purposes of experiment, with the object of finding out the conditions under which they are reflected or transmitted or refracted or totally reflected, or whatever happens to them; because it is a point worthy of investigation. A Committee of the British Association is now constituted for the purpose of requesting aid from different wireless stations, and from observers generally, in obtaining records which shall after analysis give us some idea of what is happening to the waves in the very upper regions of the air. My paper in the *Philosophical Magazine* for June, 1913, discusses some of these phenomena and the influence of sunshine.

Another method of studying the upper air is by means of explosions. I quote the following from Dr. Fournier d'Albe.

REFLECTION OF SOUND.

"Some very remarkable conclusions have been arrived at from the study of loud explosions, such as the dynamite explosion at Förde (Westphalia) in 1904, the roburite explosion at Witten-Annen in 1907, and especially the dynamite explosion on the Jungfrau railway on the 15th November, 1908. This was studied by De Quervain, who drew some maps indicating the range of audibility of the explosion. These maps show that it was heard in the ordinary way for 19 miles round. Then followed the 'zone of silence,' about 60 miles across, and then a range of abnormal audibility extending for another 30 miles. A calculation, undertaken by Von dem Borne, shows that the abnormal audibility is fully accounted for by total reflection from a hydrogen atmosphere at a height of 47 miles. On account of the fall of temperature with height, there is a gradual bending of the sound-waves (as of light-waves in the mirage), but there is a certain minimum distance within which the sound-waves can possibly strike the earth after reflection, and that distance is 72 miles, which agrees very well with observation. To get this minimum range, the sound-waves must pass upwards from the ground at an angle of 30° . Any greater or less elevation gives a longer range.

"It appears quite likely that the study of explosions will form a valuable addition to our means of investigating the upper atmosphere."

Dr. Wegener of Marburg has attempted to prognosticate a good deal about the condition of the upper atmosphere.

Fig. 3 is Dr. Wegener's diagram of the atmosphere to an enormous height. A great deal of it I should think is, necessarily speculative, but still it represents an expert opinion.

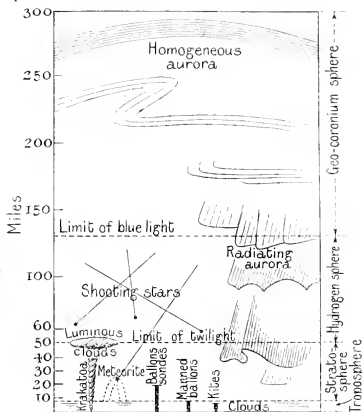

FIG. 3.—Cross-section of the Atmosphere (after Wegener).

Further information about the condition of the upper air, and recognized methods of examining it, can be obtained from a recent book, entitled "The Structure of the Atmosphere in Clear Weather: a Study of Soundings with Pilot Balloons," by C. J. P. Cave, M.A. (Cambridge University Press); which book was reviewed by Dr. W. N. Shaw in *Nature* of 18th September, 1913. The following quotations from this review will show that parts of the above diagram (Fig. 3) convey orthodox teaching.

"The investigation of the upper air is of such interest and the incidental problems which it presents are so numerous, so attractive, and, in these days of flying, so practical, that it is a matter of some surprise that there are not found more men of leisure to follow the notable examples of Professor Lawrence Rotch and M. Teisserenc de Bort in the investigation of the free atmosphere. . . . We have had to chronicle the division of the atmosphere into two distinct layers, an upper layer, the stratosphere, in which there is little or no variation of temperature in the vertical, but sensible variation from day to day, or along the horizontal, and a lower layer, the troposphere, in which the variation of temperature is greatest in the vertical and relatively small along the horizontal. . . . Ten kilometres may be taken as a rough and ready estimate of the average thickness of the troposphere with the understanding that there is a latitude of three or more kilometres to be allowed in either direction according to circumstances. . . .

"For the practical study of the dynamics of the atmosphere we are largely dependent upon observations with pilot balloons. They may be taken as supplementing

observations of clouds, and, in due time, both must be brought into relation with the observations of pressure and temperature obtained from registering balloons. It is in many ways unfortunate that the track of a registering balloon cannot always be followed by a theodolite or otherwise determined."

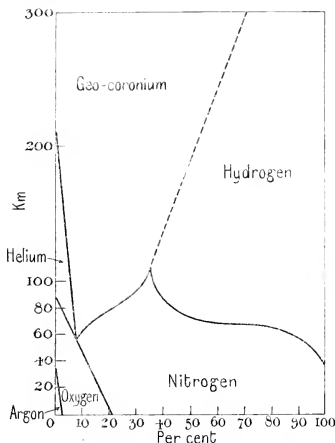

FIG. 4.—Percentage Composition of the Atmosphere at Various Heights (after Wegener).

On a similar scale of height Fig. 4 is Wegener's diagram of the chemical constitution of the atmosphere at different elevations. It illustrates what he supposes the percentage composition of the atmosphere to be at various heights. At the height of 20 miles, for instance, he depicts about 1 per cent of argon, 14 per cent of oxygen, and say 85 per cent of nitrogen. At a height of 100 miles he considers that there is practically no oxygen, about 4 per cent of helium, about the same amount of nitrogen, a great deal of hydrogen, and some of the speculative gas which he calls geo-coronium—of constitution akin to the material in the corona of the sun which gives the coronium line in the spectrum. The diagram, of course, only represents percentages, not actual amounts. The actual amount of the lighter gases must anyhow be exceedingly small.

It must also be understood that I do not vouch for their presence at all in any appreciable quantity. I see many reasons against it. The amount of hydrogen, for instance, must depend on the rate of supply, e.g. from volcanoes, and the rate of escape. The latter datum, on Dr. Johnstone Stoney's theory, is more definitely known than the former. Stray wisps of perhaps frozen gases may exist, orbitally moving through space, and the earth may pick up not merely stones, iron fragments, and dust—but other sometimes less innocuous things, as indeed Lord Kelvin once suggested—a line of thought which the strange occur-

rences of new diseases from time to time must do something frequently to stimulate.

ARTIFICIAL ELECTRIFICATION.

I must go on to the subject of artificial interference with atmospheric electricity. In 1883 and 1884 I was investigating dust and its electrification, and I gave a demonstration at a meeting of the British Association at Montreal—where Lord Kelvin was present and was very enthusiastic about it, as he always was for any new experiment—showing the effect of electrification on dusty or smoky air. The particles aggregated together into a kind of visible lumps or snow—cohering somewhat as iron filings do near a magnet—and fell or were deposited upon the surface. The experiment has become so familiar that I shall not show it, but I want to emphasize the fact, also exhibited at the same time, that not only solid dust shows this effect, but liquid dust, that is to say, a cloud of visible steam. If a discharge is passed from a point into a bell-jar full of "steam" from a kettle the drops coalesce; they coalesce together and rain is obtained. The microscopic globules become bigger and they can be seen falling as a Scotch mist.

Strange though it may seem in this country, most of the countries in the world suffer more from drought than from too much moisture, and would benefit by being able to produce rain. If there are no clouds it must be hopeless; but it is said to be irritating, in a place where they want rain, to see clouds assemble and then disperse without any water falling. If it were wanted at that time to cause rain, I take it that by ascending a mountain and flying a kite—or perhaps a kite alone would be sufficient to reach the lower clouds—and by discharging sufficient electricity into those clouds, I cannot but suppose that the drops would behave there as they do in the laboratory, and that at any rate some of them might be stimulated to coalesce and to fall; and I imagine that when once the process had begun it might spread and that a real rain shower might be obtained. There are many questions about that, as to the amount of energy and so on. I feel, however, that it is a matter for experiment, and that until one has experimented on a large scale one cannot tell what will happen. I must confess that this lecture is not a record of achievement but is rather a programme of agenda.

I think that those experiments ought to be tried, and that we cannot tell what will happen until we do try them. But they will be expensive, because it is no use trying the thing on a laboratory scale when we are dealing with the forces of Nature; we must cope with them, and we must expend a certain amount of money and invest a certain amount of capital in doing it.

But what about the best mode of supplying electricity for this purpose? The old method is by the static machine, the convective machine, the Holtz, the Voss machine, or the Wimshurst. It is surprising that no kind of static machine has been taken up by engineers and made practically efficient. I think I am right in saying that, although there have been decided improvements; but I take it that such machines will always be rather inefficient in the matter of strength of current, because the current at one part has to be carried by mechanical motion, and the current that can be carried by the few electrons that constitute an ordinary static charge, with the rapidity of any

feasible mechanical motion, is extremely small as compared with what can be carried by the immense crowd of electrons in a metallic conductor. Practically the quantity that can be set going in that way, mechanically, is very minute as compared with what can be driven by a dynamo.

Then there is the chemical method—the ions in liquid, the battery method, the voltaic method; and it may be that a very large battery with a very large number of cells may be adapted to this purpose—a utilization of the ionic procession in liquids. The difficulty now is not the quantity: there is plenty of quantity: the difficulty is to get sufficient potential. The same thing must be said of a dynamo. There we have an electronic procession in the metal. There is no difficulty about its speed or strength of current, but great difficulty about the insulation when the voltage is high. The method which I have found best so far has been the method of a transformer and valves. We transform up to any required potential, and then bank up the electricity that is supplied by means of electric valves.

To this audience I need hardly explain the meaning of an electric valve. It is a device which transmits electricity in one direction only, so that up to a certain limit it is passed through easily and is prevented from coming back again—exactly like a valve. In that way a Leyden jar can be permanently charged by connecting it with an induction coil, although it is short-circuited by the secondary winding, and can remain so, when a valve has been inserted. Charges are put into it intermittently, and after the manner of a water-ram they pile themselves up until they cause the jar to overflow; valves bank up the charge, as it were. Here is an arrangement by which an alternating dynamo can be used to charge one conductor negatively, which may be earthed, and another conductor positively, which may be taken up into the upper atmosphere. It is an ordinary arrangement with four valves, or four sets of valves.

I might show the detail of the valves themselves, but I have published this in the *Philosophical Magazine*,^{*} and I will not take time over it now.

This slide shows a view of them. They have a very large and open cathode and a very small and constricted anode. That is not all that can be said about them, but that is the basis of them.

Here is an arrangement for supplying high-tension electricity where it is wanted for any particular purpose. If excessive potential is required a row of valves is needed, because although they each bank it up, yet they can be burst back, so to speak. If an enormous potential is wanted it is necessary to have a series of them.

ELECTRIFICATION OF CROPS.

In the matter of electrification applied to horticulture and agriculture Lemström is one of the pioneers. Lemström[†] experimented ever since 1885 on the influence of artificial electric fields or currents on the growth of plants. The influence is, he says, in general highly beneficial; for instance, it shortens the time required by strawberries and raspberries to ripen, and increases the yield. It may, how-

* SIR O. LODGE. "The Mode of Conduction in Gases, illustrated by the Behaviour of Electric Vacuum Valves." *Philosophical Magazine*, vol. 22 (Series 6), p. 1, 1911.

† S. LEMSTRÖM. "Experiments on the Influence of Electricity on Plants." *Report of the British Association for the Advancement of Science*, 1898, p. 808.

ever, be injurious, especially during bright days, unless abundance of water is provided. Lemström believes atmospheric electricity plays an important part in the growth of vegetation in high latitudes, and he assigns a special rôle to the needles of fir and pine-trees. E. H. Cook^{*} describes experiments somewhat similar to those of Lemström. He observed a beneficial effect on plants grown under a pole—especially the negative pole—of a Wimshurst machine or an induction coil. Cook refers to experiments aiming at the direct utilization of atmospheric electricity.

Now the valves that I have been speaking of afford a method of applying high-tension electricity in a more engineering way than hitherto, and to some of this work in agriculture they have been applied by the Agricultural Electric Discharge Company of Gloucester.

The slide shows a practical instalment in a shed for the purpose of electrifying the atmosphere; it is as supplied for agricultural purposes for electrifying crops. The wire from them goes out into the field, through a very elaborate insulator. An overflow or emergency spark-gap serves to measure the potential of the conductor. It is not generally actually sparking, but it can be made to spark by turning a handle so as to diminish the gap, just to see if sufficient potential is maintained, and that there is not too much leak on the conductors out of doors. The spark-gap acts as a sort of safety valve too. The wires are supported on posts by very special insulators provided with an oil cup to withstand these high potentials. The wires which are suspended over the field are not attached to the main insulator at all, except through ebonite rods or looped porcelain insulators. There are various devices for assisting the insulation.

In a field near Bevington, in Worcestershire, where this method has been applied to the electrification of crops, wheat has been grown under wires stretched on poles. About 1 pole to the acre suffices, or say 70 yards apart. It began in 1906, and the effect in nearly all the years has been a decided increase, I am told, except in 1911, when the electrified plot and the control plot both gave about equal amounts. There was drought that year; it was an exceptionally bright year, and there was plenty of sunshine. That is what I think our experience leads us to hold, that the electrification supplements the sunshine and is most required when the sun is feeble. When the days are overcast that is the time when they require a stimulus, but if the sun is particularly bright then by supplying positive electricity artificially also we should be over-stimulating the crops.

The gradient of potential artificially supplied is the fine-weather gradient. It has to increase the downward current. It will be remembered that the natural downward current is extremely small—about one micro-ampere per square kilometre, but artificially we can get it to 10,000 times as much in some cases. Even so the current downwards is extremely small. I think the effect must be due to the charge rather than to the current. It may have some nitrogenous manuring effect, but it can hardly supply an appreciable quantity of extra energy.

The wires supported by the poles can be high enough not to interfere with agricultural operations. What we

* E. H. COOK. "The Action of Electricity upon Plants." *Report of the British Association for the Advancement of Science*, 1898, p. 809.

use are thick wires from pole to pole and then a number of quite thin wires across between the thick ones. We do not use points because we find that points screen each other, and they are not necessary if a thin enough wire is used. Cotton-covered wire discharges singularly well, except in wet weather; and in wet weather, or in weather in which the electricity is most required, the difficulties of insulation are naturally greatest.

Another difficulty is the screening of the control plots. We have an area under the wires and somewhere near it—as near as possible because we want the soil and conditions to be the same—we have another area not under the wires for purposes of comparison. But naturally enough it is found that the electricity which has been discharged from the system of wires blows down wind over the control plot, if it is in the direction of the wind, and tends to stimulate that plot unduly and to make them both virtually electrified. A farmer on whose ground the experiment is going on tells me that both the electrified and the unelectrified plots have given more than the average yield, but it does not make a good differential test. Screens are being erected to try and screen off the one from the other, but, as is doubtless known, it is not at all easy to screen atmospheric electricity: I have blown electrified air through fine-meshed wire gauze. At the same time a wire netting screen will to some extent protect the control area, especially near the screen, but at a distance the electrified air seems to go over or round, and we find a good deal of it down the wind, even at a distance. Professor Priestley of Leeds has called special attention to this fact.

As to the nature of the effect on plants, that is a botanical question which I am glad to know is being taken up by Prof. Priestley, Professor of Botany at Leeds University. He became interested in the experiments while he was at Bristol and has gone into the matter very thoroughly and has initiated experiments of his own. He makes certain suggestions about the possible ways in which the electrification may act, and points out that there are so many different things which may happen in a plant. In the *Annals of Botany* for January, 1914, there is a paper by him in conjunction with Mr. Knight "On the Respiration of Plants under Electrical Conditions." In a former paper he says: "There are so many processes at work within the plant, of vital importance to it, which may be altered in quantity and quality by the application of electricity, that only laboratory investigations of an extensive kind can help us to understand the effect of placing a high-tension discharge above the plant, and of the resultant increase of the electric current through the plant to the ground. Thus in this country and elsewhere, at the present time, work is in progress upon the effect of such an electrical discharge upon the respiration of plants, on their synthesis of food, on the rate of evaporation of water-vapour from the leaf, and on many allied problems."

In the experiments which have so far been made, "The actual strength of discharge, as determined by the number of thin wires above the crop and the potential they are raised to, is not decided by experimentally determined necessities of the plant; the current supplied is that which proves most practically convenient. The sign of the dis-

charge may be inadvisedly chosen. Positive discharge is used, but negative has never been adequately tried since the time of Lemström's experiments with far inferior apparatus."

I may conveniently add some further particulars recorded in the same article: "Experiments in both these branches of work are in progress at the University of Leeds—the laboratory work with the aid of a Lodge-Newman high-tension discharge apparatus, and the field experiments at the University experimental station, the Manor Farm, Garforth, where land has kindly been placed at my [Professor Priestley's] disposal by the courtesy of the Yorkshire Council for Agricultural Education."

Miss Dudgeon has also been conducting experiments at Duffries, with the assistance of Mr. Cameron, the farmer on whose land at Lincluden Mains the crops are grown.

"Usually the overhead wire network itself consists of wire of two gauges (up till now galvanized iron wire has been used); the larger wire (No. 11) runs in two parallel strands across the strip to be electrified, and at every ten yards the thin (No. 24) wire spans the space between them, and from this wire, owing to its thinness, the high-tension discharge is continually leaking down to the plants beneath. As these wires will stand considerable strain, they can be drawn taut by means of the usual strainers, and as the poles stand some 16 ft. above the surface of the ground, the wires, in spite of their inevitable sag, remain well out of the way during all farming operations.

"The system of overhead wires is borne upon larch poles, crowned by specially constructed large insulators, in which the leakage, due to moisture condensed at the surface, is counteracted by an oil cup on the inner protected surface. The charged wires do not touch the insulators, but are suspended at some distance from them by means of some special insulating medium—rods of ebonite, chains of porcelain insulators, and other methods have at various times been used. If care is taken over this question of insulation, especially in obtaining adequate insulation where the high-tension wire leaves the shed and where the network is supported by the pole over the field, then it is possible to keep the overhead network continuously charged to very high tensions, such as 100,000 volts.

"In the various experiments carried out with this apparatus during the last seven years the potential of the overhead system employed, as measured at the spark-gap, has varied between some 60,000 volts and 100,000 volts."

That is the potential usually employed, between 60,000 and 100,000 volts. Of course the actual strength of the discharge may be varied, but we do not know sufficiently what the requirements of the plants are.

That is one of the difficulties in all these agricultural experiments, that they are so slow. There is no immediate response. We have to go through the whole season before we know that what we have been doing is correct; and when the farmer has found out that positive electrification gives him an increased yield it is difficult to get him to consent to an experiment with negative electrification. This is extremely natural: let it not be supposed that I am criticizing. On the contrary I wish to express admiration for the enterprising and scientifically-minded farmers who have been good enough to allow experiments to go on on their lands. I wish specially to mention the local help

* J. H. PRIESTLEY. "Experiments in the Application of Electricity to Crop Production." *Journal of the Board of Agriculture*, vol. 20, p. 582, 1913.

of Mr. Bomford of Bevington Hall, Salford Priors, near Evesham, Worcestershire, in this way. The trouble caused must often have been considerable, in these early and experimental and small scale trials; for a 20 or 40-acre plot, though more than a laboratory experiment, is still a small scale trial. Not wheat only has been tried, but other crops, which will be referred to in their proper place. I am not at all sure, but I am inclined to think, that leguminous plants behave oddly in this connection: they seem to be quite as well satisfied with a negative electrification and do not care about the positive. One year we did have a negative electrification over wheat, by accident, in a place that was not properly controlled, and it was not a satisfactory year. On the whole I am inclined to think that the natural electrification of the atmosphere is what wants artificially intensifying at times; and certainly as far as the experiments go—those which my sons have been conducting with Mr. Newman—when this is done the crops are improved. Mr. Newman of Gloucester is the engineer of these operations; he has set them going and we have only supplied the apparatus for the high tension and supervised its working. They certainly find that the crops are improved. Strawberries, for instance, are earlier and also more plentiful.

It may be interesting to quote here some of the methods used for electrical measurements in this work. Dr. Priestley reports*:

"Suffice it to say that after trying several methods to obtain the required electrical measurements, the most practical and useful apparatus proved to be an electrometer with two different pairs of aluminium leaves giving a range of from about 80 to 800 volts. For determinations of atmospheric potential the electrometer was simply connected to a flame collector mounted on an ebonite stand; the electrometer itself stood on the field on a level glass plate, and care was taken that the insulated wire between electrometer and collector was not allowed to approach too close to any blades of grass.

"For the determination of the current density in the air a flame collector was replaced by a flat metal collector of known area and a condenser of known capacity connected up with the electrometer, the outer cases of both electrometer and condenser being connected to earth. The average time required for the electrometer to take its full charge and discharge to earth was then taken, and from these data, knowing the capacity of the whole system to be charged, it was possible to calculate the strength of the current per square centimetre at the point where the metal collector was placed in the air.

"When these data were obtained it was possible to compare the electric current in the field under the discharging wire with that present under the normal atmospheric conditions.

"This natural flow of positive electricity downwards through the air is of the order of 10^{-16} ampere per square centimetre. . . . In the conditions obtaining under the wires the current was increased to a value of from 10^{-12} to 10^{-11} ampere per square centimetre. That is to say, the current, under the electrical treatment, is raised to some 10,000 times its normal value.

"... It is still a remarkably low figure, however, and suggests that if effect is produced by such treatment it is to be looked for in the more direct utilization of sources

of energy already available, under the stimulating action of the electric current.

"As soon as the current under the wire had been determined, measurements of the current in other parts of the field at varying distance from the charged overhead wires were made. These determinations soon showed that the effect of the discharge could by no means be looked upon as restricted to the area under the wires, but that on a still day a current at least a thousand times the normal was to be found at a distance of some 30 to 40 yards out from the wires, while on a windy day, even though the wind was comparatively light, the current travelled out away from the wires down the wind for quite unexpectedly long distances.

"From these figures it will be seen that a control area unaffected by the discharge cannot be obtained within hundreds of yards on the leeward side of the electrified area.

"The immediate problem is the provision of a genuine control area, near enough to the charged wire to be under similar conditions to the electrified area as regards soil, climate, and exposure. This is by no means an easy matter, but experiments at present in progress make one hopeful that partial success may be obtained by placing a netting of galvanized iron wire, 10 or 12 ft. high, between the control area and the charged wire. The netting will need to be of comparatively close mesh, but for the purposes of a critical experiment the difficulties in the way of erecting such a netting can readily be overcome. A more serious difficulty is that even with this barrier inserted, preliminary observation suggests that it will still be necessary to stop the discharge whenever a strong wind is blowing from the electrified area towards the control."

Concerning experiments locally conducted in Worcestershire, Mr. J. E. Newman has favoured me with the following particulars, under date 20th January, 1914:—

"The 1913 results (trials with potatoes only) are not yet available, as the crop has not been sold, and is only weighed as it goes away. Neither are Mr. Low's figures ready.

"The most complete experiments are those on wheat (all at Mr. Bomford's, at Bevington)—

					Increase.	
1906	...	Field A	39	% (Red Fife)
					29	" (White Queen)
1907	...	Field A	20	"
1908	...	Field B	24.3	"
1909	...	Field C	23	"
1910	...	Field C	22	"
1911	...	(Drought) Spring-planted wheat.	...	0	...	Yield 16 bus. per acre both areas
		Field A	
1912	...	Field A	20	"
1913	...	No wheat grown.	

"The unelectrified yields have always been from 30 to 36 bushels per acre—the average yields of the whole country—with the exception of 1911.

"The power consumed is 500-750 watts, for an area of 20 acres.

"I am sorry I cannot give the total hours run, as the log-book is at Mr. Bomford's; it averages 6-8 hours per day during the growing period. The discharging wire is No. 24 silicon bronze, spaced 10 yards apart. Tension = 3/4-in. spark to earth, between 1-in. balls."

* *Journal of the Board of Agriculture*, vol. 22, p. 582, 1913.

The current under the electrical treatment is raised to some ten thousand times its normal value. That is not large: it is only 10 milliamperes per square kilometre. That is still a low figure, because the normal value of the current, as I said, is absurdly minute. It is a low figure in the matter of energy, even at 100,000 volts: not more than 4 actual watts to the acre. The process does not consume much energy, for although the potential is high the actual amount coming off the wires is small. A very moderate amount of power will cover a considerable acreage, say 20 acres, even with all the sources of loss; a 2-h.p. oil-engine is found sufficient for a farm.

Another place where these experiments are going on is Mr. Low's farm at Balmakewan in Scotland; and they are also going on to some extent on the Continent. More experiments of this kind are very desirable, and that is one reason why I bring the subject before this audience; experiments require repetition in a great many places, because they are so slow, and it is necessary to have a large number of variations going on concurrently to gain experience. I believe that they would be conducted best not on a large scale, but on a small scale in a greenhouse. But some collaboration with a chemist or botanist, or both if possible, as well as with an electrician, is required. It is an electrical problem to look after the insulation; and also to see that these high tensions are safe. With regard to Mr. Newman senior's greenhouse at Bristol, he has it so arranged that by opening the door the wires automatically earth themselves—one being attached to the door. Otherwise it would be dangerous to go in.

There is a great deal more to be done in this direction, and I bring the whole subject forward as an agenda, something that might be worked up.

POSSIBLE INFLUENCE ON WEATHER.

I want to say one word more about a much larger scale work than this of agriculture. I say nothing about fume deposition at all, this time; that is another matter, though it is closely allied to the subject. I say nothing about the electrification of fume and dust in factories, but I do want to say something more about the electrical aggregation of drops and a possible effect on weather. I have already said that it is uncertain as to which is cause and which is effect, but if the weather is influenced by natural electrification of the air, then that electrification ought to be taken in hand. If we want rain we should reverse the sign and send up negative electricity; if we want fine weather we should send up positive electricity. The difficulty is to get it high enough up and in sufficient quantity. It must be an expensive experiment; but on the top of a mountain, with kites and balloons, and with proper engineering arrangements for permanently doing whatever is desired in the direction of getting up a sufficiently high tension and discharging an adequate quantity—adopting whatever means is best adapted to that end—something is bound to happen. A thunderstorm might be produced; at any rate that would be an interesting thing to do. I see no reason why experiments should not be made on a sufficiently large scale to see what happens.

I do not know whether members remember a very early novel by Mr. Marion Crawford where he makes his hero devise a peculiarly efficient galvanic battery. He does not care much about considerations of energy: a number of

cells in series gave him not only a tremendous potential, but also a tremendous current. He surrounds the hills with wires on little insulators, little things that would not insulate really at all adequately, and he electrifies the whole. He gets all sorts of curious effects. He brings on a thunderstorm certainly, but he brings on many other things, for which I will refer members to the book. "With the Immortals" I think was its title; it is a long time since I read it.

I feel that there are parts of the earth, and parts of the earth belonging to the British Crown, which would be the better for some weather control.

And there is one other suggestion that I want to make, which is perhaps rather an absurd one. I have assumed that we proceed with artificial electrification, on the basis of directly trying to assist, shall we say, the sun in maintaining the positive gradient, for the good of plants or for any other purpose—or else on the basis of interfering with the sun and supplying negative electricity when the sun is supplying too much positive. Is there any other way? Is there any way of artificially interfering with, and deflecting, some of the particles received from the sun? We get, as I hinted, the positively electrified solar particles mostly down in the tropics, the alpha rays; and the negative charged particles go to the Poles. Why? Because the earth is magnetized. Supposing we reversed the magnetism of the earth! Or supposing we interfered with the magnetism of the earth! Then we should get a number of those negatively-charged particles down where they do not go now. Help them down by a large magnet! Surround the earth with a girdle of very thick copper. Not on the equator, because that is too far round, but up nearer the North Pole. Send a very big current round it. It is a matter of arithmetic what current will suffice; but the doubt about the arithmetic is this: What does the earth consist of? If the earth is mainly native iron, and if its temperature, or its temperature over vast regions, is not above the critical point of iron, the permeability of the earth will be very considerable and a million amperes will do something. But if there is no iron in the earth, or if it is above the critical point, then that current would not be sufficient. At any rate we could ascertain its condition by trying to re-magnetize the earth. It seems an absurd thing to put anything like a bar round the earth, but it is a familiar fact that four metal bars—400 I should think—run the whole length of England, all artificially put down. They are called lines of rail. And they stretch all across America. They do not yet go from the Cape to Cairo, but they will be going across Persia to India. People can put down large masses of metal when they have good reason for putting them down.

With that rather absurd suggestion, which perhaps ought not to be taken too seriously, about influencing the cosmic causes of the distribution of our atmospheric electricity (for I think really more seriously of the direct electrical method of more local attack) I will conclude this Kelvin Lecture.

Dr. R. T. GLAZEBROOK: I presume that it is because I had the honour to deliver the last of these series of Kelvin Lectures previous to that of Sir Oliver Lodge that I have been invited this evening to express to him the

Dr. Glazebrook.

Glaze-
k thanks of this meeting for the lecture which he has given to us, and to ask that he will most kindly fulfil that promise which he has already made that the lecture shall be printed in the *Journal*. I am afraid that the President gave to our lecturer this evening an impossible task if he really suggested to him that he was to deliver the Kelvin Lecture without referring to the work of Lord Kelvin. I do not think his letter exactly took that form. But no doubt he wished to give Sir Oliver a free hand in the subject that he selected for the lecture, and I am sure we are all very glad that that was done. The Kelvin Lectures of the past have dealt mainly with some specific part of Lord Kelvin's work. Obviously it is not possible that that should always be continued, and the connection which Sir Oliver has shown between the commencement of the work of the measurement of atmospheric electricity and Lord Kelvin is surely sufficient to justify him in talking to us to-night on this most interesting and important subject of atmospheric electricity. He has told us that he was not giving us a résumé of past achievements but a programme for future work. We have to thank our President for advance along many paths of progress, and among those I should like particularly to refer to the inauguration of the Research Committee of the Institution. May I suggest that this lecture which we have had from Sir Oliver Lodge may perhaps be the first of those reports on the state of science about which we have heard something at the Council this afternoon, and may lead to future research work of real national importance on the subject that has been brought before us. We are always glad to see Sir Oliver Lodge here; we are always pleased to listen to him, and we recognize on all occasions the inspiration of the words that come from him. I will only ask you, therefore, to offer a very hearty and cordial vote of thanks to him, and to request him to allow this lecture to be printed in our *Journal* in the usual way.

Thomp-
Dr. SILVANUS P. THOMPSON: I am delighted to second the motion which has been proposed by Dr. Glazebrook, to convey our thanks in the heartiest way to Sir Oliver Lodge for the lecture which he has delivered to us. We have been led into a branch of electrical studies with which probably comparatively few of us are familiar. Indeed, it sounds almost like the founding of a new science—that of electro-agriculture—to which we have been treated to-night. What will be thought a hundred years hence by those who turn up the *Journal of the Institution of Electrical Engineers* for the year 1914 when they discover how little we knew about electro-agriculture, which by then will have transformed the face of the earth! People have been at it for a long time. I have in my possession a delightful old engraving more than a hundred years old which represents an electrical greenhouse provided with wires and spikes for electrifying the plants in pots, and somewhere in the background someone is turning the axle that drives a pair of curious old electrifying machines, and the plants are supposed to be enjoying it. We have heard of the aurora borealis, but I think not even Sir Oliver Lodge has alluded to the very remarkable fact that in the short summer of the Arctic regions they can gather a larger number of crops than we can in our lower latitudes, or than can be gathered even in still lower latitudes nearer the equator. Why is it that in the Arctic regions in that short summer the plants grow so exceedingly quickly?

Dr. Thomp-
son Why is it so if indeed the aurora borealis is not accountable for the stimulating effect? Now in those old attempts that were made a hundred years ago to electrify plants with the old electrifying machines they failed, and failed for very obvious reasons. They had never thought of those things that have been brought so excellently before our attention to-night, the hints which Nature and modern electrical art have given towards understanding natural processes. Did it ever occur to any of us before now what was the use of points on the leaves of plants? Well, we know. There is the picture that was shown to us. We do not want to be sending discharges from spikes to the plants, but we should let the plants use their own spikes in their own natural way, and simply help them by a larger potential gradient. What did we know about potential gradients 50 years ago? Practically all that we knew was what we learnt from Lord Kelvin's measurements. So once more the old truth is justified that if we examine patiently and without hope of reward into the facts of Nature and correlate them and make them scientifically available, they justify themselves in the long run. And what seemed to be one of the most unprofitable researches, the mere measurement of difference of potential between one height in the atmosphere and another, turns out to be the key to an important industrial application years after. Who would have thought in experimenting with pretty vacuum tubes and an induction coil, and sending sparks through, and finding—by accident probably—that it was rather easier in some cases to send a spark through the tube from one end to the other than it was to send a spark from the other end to the one, that in that incidental fact there was the beginning of something which might be improved and magnified, something which, with careful work in the Birmingham Laboratory, might be developed into an electric valve; and with the electric valve came the possibility of piling up the potential and obtaining these charges at high voltage with a comparatively simple apparatus! We have been told what is the voltage that is employed in these agricultural experiments, but are there not experiments going on on almost as large a scale even now which might be used for agricultural purposes? There are such things as transmission lines in other parts of the country than this, where people are working at 60,000 volts, 120,000 volts, and 150,000 volts. Is the vegetation improved underneath those? It ought to be under certain circumstances. [Sir OLIVER LODGE: It is alternating current.] What are the circumstances? We are told that it is alternating current, but it is not all alternating current. Mr. Highfield will at once challenge that. If we have a non-alternating-current line, is the vegetation underneath that line improved? Is the vegetation improved if the electrification of the line is positive? We should like to know. Moreover, there are other ways in which the ionization of the air can be improved, when it occurs without being intentionally brought about. We have had a most suggestive lecture. We have been stimulated by the high potential—not too high over our heads for us all to enjoy it—of the intellectual atmosphere. Doubtless we may look forward to many and great results from the delivery of this lecture. There are many of us here who are keenly interested in some little part perhaps of the subject. Perhaps there are some here who take a direct interest in agriculture. Surely they

will give their help to give publicity to this great fact that is already established—that electric discharge under proper conditions, under scientific control, with an understanding of the natural processes that are going on, does improve the output of the crop. It is only a question of learning a little more as the seasons roll by, and of finding men willing to make the venture of spending capital upon it. There is nothing needed more than that to put the discovery into effective operation. My mind goes back some 25 years, possibly more, to the time when electric lighting was nearly new, when the late Sir William Siemens—the first President of this Institution—produced things from his experimental farm, if I might call it so, from his estate in the South of England, where he was stimulating the growth of maize and wheat, and other crops, not directly by electric discharges, but by giving them an extra dose of electric light at night, prolonging the daylight for them and increasing their growth. Unhappily it was not found to pay. But now we have a new departure in the novel science of electro-agriculture, and having had it so admirably expounded to us in a way that we have all been able to follow, surely we may look confidently for great results. I venture to think there will be direct results from Sir Oliver Lodge's address to us. We recognize that the memory of Lord Kelvin has been well and worthily honoured by his latest exponent.

The Resolution was then carried by acclamation.

SIR OLIVER LODGE: I thank members very much for their reception of me. It is a great pleasure to meet so many electrical engineers and to talk to such an audience. I should have liked a little more time, but I took up quite enough. I wish also to thank the two Past Presidents for their eloquent speeches. I just wanted to say one word suggested by the remarks of Dr. Sylvanus Thompson. We have found hedges underneath a high-tension wire that was leading to another part of the farm grow very decidedly. It happened quite unintentionally. They sent up shoots decidedly higher than another part of the same hedge. I had some other lantern slides showing those effects but I thought it better not to go through them all.

I hear that some attempts have been made with high-tension alternating current—utilizing a kind of Tesla effect. I have not heard that they have been successful, and I should not anticipate that they would be. At any rate I think that a charge of one sign will be more efficient. The natural high-tension effect spoken of by Dr. Thompson has, perhaps, been observed. The President tells me it has been observed in some cases; that under a wireless area, the area of a wireless Marconi installation, the grass is found to grow better than it did before. I expect that, when looked for, these effects will often be found. I echo the wish that has been expressed—and that is one reason why I brought this forward—that we shall get more investigators into this field. The field is perfectly open to anybody. The experiments are interesting, though rather slow, but with all the skill here present they might be put into operation, and I hope that to 10 years hence we shall get a very large number of positive results.

(Communicated): The American Consul in Birmingham, Mr. Halstead, has kindly sent me an extract of the *American Expositor* of recent (but to me unknown) date, which

contains an account by Dr. H. G. Dorsey of some initial small-scale experiments conducted in America. And, inasmuch as enquiries are often addressed to me about the relative advantages of other methods of treatment, especially as to the advantage of earth currents sent among the roots of plants, I think that a quotation from this paper may be permissible and interesting, although the experiments that it records are of a very initial and tentative character. But the whole subject is essentially new, and many things must be tried. The method advocated by me was not employed by these experimenters, but a Tesla alternating discharge was one of the things tried and apparently gave good results. It is noticeable that electricity applied directly or indirectly to the soil or roots did no good at all; it was only good when applied to the aerial portions of the plant.

"In order to advance the work of intensive culture which might be applied in the Boys' Gardens, President John H. Patterson, of the National Cash Register Company, suggested among other things that the effects of electricity and artificial illumination be tried. The following tests were made possible at Moraine Farm through the generosity of its owner, Mr. E. A. Deeds, vice-president of the company. Moraine Farm is situated about four miles south of Dayton, Ohio, in the fertile valley of the Miami River, and is equipped with almost every form of modern electrical apparatus which may be applied to farm and residence use.

"During January and February of 1913, preliminary experiments were carried out by Mr. F. O. Clements, the company's chemist, and the writer, in the greenhouse of Moraine Farm. Seven plots were prepared about three feet square each, and were partitioned from each other by thin wood partitions in such a manner that each received full sun and sky light. In order that the soil might be uniform in the different plots, it was thoroughly mixed and sited together and then placed in the different plots to a uniform depth of about six inches.

"Plots 6 and 7 were subdivided into four individual boxes each one foot square, which were separately insulated with porcelain insulators and supplied with carbon electrodes on the inside at opposite ends of each box. To these carbon electrodes was applied both alternating and continuous current. In Plot No. 7, 60-cycle alternating current of 110 and 220 volts was applied to one box and 175 volts from a dry cell was applied to another. The other two boxes were similarly excited, but only after germination. The currents in the eight boxes varied from 0.003 ampere to 0.07 ampere, depending on whether the boxes were freshly sprinkled or nearly dried out. There was no apparent difference between the effects of alternating and continuous current. All 8 boxes maintained a temperature a few degrees higher than the other plots, due to the heating effects of the current in the soil. The results were uniformly poor, germination being retarded and growth being stunted. Later experiments were tried in cigar-boxes with voltages from 3 to 8 volts supplied by dry cells, the currents varying from 0.0007 to 0.05 ampere. These tests also showed evil results instead of good and from our standpoint earth currents proved a complete failure, and Plots 6 and 7 were abandoned.

"Plot 1 was excited by high-frequency currents from a

small Tesla coil. A small transformer raised 110 volts 60-cycle alternating current to 5,000 volts, and charged a condenser of tin-foil and glass plates which discharged through the primary of the Tesla coil and a spark-gap. A network of No. 30 B. & S. gauge wire was stretched about 15 in. above this plot and connected to one terminal of the Tesla coil, the other terminal being connected to a wire screen which was buried in the bottom of the plot. The transformer and boiler took about 130 watts and were operated for one hour each morning and evening. The potential difference between the soil and overhead wires was about 10,000 volts, and the frequency may be about 200,000 periods per second.

Plot No. 2 was illuminated by a 100-watt tungsten lamp with ruby bulb 3 hours per day, beginning at sundown. Plot No. 3 was illuminated by a Cooper-Hewitt mercury-vapour lamp 3 hours per day, beginning at sundown. Plot No. 4 received no artificial stimulation and was used as a control plot, so that comparisons might be made between the plots receiving excitation and one receiving none. Plot

stimulation. No stimulation was attempted on Plots 1 to 5 until after germination. The seeds were planted on 16th January, and on 29th January stimulation was begun on Plots 1, 2, 3, and 5. About 3 weeks later 10 plants each of radish and lettuce were selected at random from the 5 plots and weighed as shown in the table appended.

"From this table it will be seen that the high-frequency currents caused a greater increase in yield than any of the other methods of stimulation. Ruby light ranged second for radishes, but violet light ranged second for lettuce. The electric sprinkling system was worse than no stimulation at all. Comparing the high-frequency plot with the control plot we find that the edible portion is 75 per cent greater with the lettuce.

"We next attempted to repeat these experiments using tomatoes and cucumbers, but were prevented from getting any results because of interruption by the Dayton flood.

"The results obtained from the high-frequency tests were sufficiently encouraging to warrant us in starting something on a larger scale. A 2-acre plot of good soil was selected in a flat field to be used as a house garden, and this was arranged to be sprinkled by an overhead sprinkling system. Pipes were suspended from a catenary suspension system 14 ft. above ground, the pipes running east and west 200 ft. and spaced every 50 ft. north and south for a distance of 400 ft. In the north-east corner of this garden seven wires of No. 12 B. & S. hard-drawn copper were stretched north and south 200 ft., the wires being 9 ft. above ground and 15 ft. apart. The ends of the wires were attached to insulators on top of 4-in. gas-pipes set in concrete, and at the middle they were supported by suspension insulators from one of the lines of sprinkling pipe. Both types of insulators were built for 60,000-volt power circuits. This system was sufficiently high so that the soil could be ploughed with horses. It should be noted that the high-frequency system was independent of the sprinkling system. Occasionally the two were run at the same time, but not often.

"At the eastern edge of this plot was built a small transformer house, in which a 7.5-k.v.a. transformer stepped up 220 volts 60 cycles to 11,000 volts. A choke coil was placed in series with the primary. The secondary was connected to a spark-gap, and shunted across this was the condenser in series with the primary of the Tesla coil. The primary of the Tesla coil was made of 8 turns of No. 0000 wire, and the secondary consisted of 75 turns of No. 14 B. & S. gauge on a wooden drum 15 in. in diameter and 18 in. high. The primary and secondary were both immersed in a 50-gallon stoneware jar full of transformer oil. The bottom end of the secondary was connected to the pipes of the sprinkling system, which furnished an earth connection, and the upper end of the secondary was led through a 60,000-volt bushing from the transformer house to the middle of the antennae, which were connected together by a wire running east and west. The spark-gap was formed of two rectangular boxes of thick copper, with two faces parallel and 1/4 in. apart. The boxes were hollow and filled with water, and gave excellent service as a stationary spark-gap.

"Considerable difficulty was experienced in getting the system to work properly. Condenser plates were continually breaking down until the condenser was built of old photographic plates 8 by 10 in., two glass plates, and

No. 5 had a wire network buried in the bottom which was connected to the negative terminal of a 110-volt continuous-current circuit. The positive terminal was connected to a small sprinkling can which had a carbon electrode in the middle insulated from the can itself. A small insulating stand was provided on which this sprinkling can was placed. The can being filled with water was then electro-lyzed for about 3 minutes. During this time the temperature of the water would rise from about 70° Fahr. to 90° and become considerably gaseous by the evolution of oxygen and hydrogen from the water. While still bubbling, the negative terminal to the can was opened and the plot sprinkled, the idea being that current might flow from the can through the streams of water to the soil.

"All of the plots were planted with radish and lettuce seed, samples of which had previously been tested for germination to make sure they were good seeds. No germination tests were available in the plots because mice ate several of the seeds at the beginning of the test, so that the results show only the effects after germination. All plots received exactly the same treatment other than the

then a sheet of tin-foil. Two boxes containing about 300 glass plates and each filled with transformer oil gave a good condenser of about 1/10 microfarad capacity which did not break down, and it was not even necessary to remove the coating from the plates. Trouble was also experienced in finding a suitable container for the Tesla coil immersed in oil until the stoneware jar was thought of. Taking into account the various delays, it was the latter part of July before the system could be considered in perfect working order. At that time it was giving the full 50,000 volts, as measured by the needle spark-gap between the antennæ and earth. For several weeks previous to that time, voltages of from 10,000 to 20,000 could be maintained. The garden was electrified daily from 6.30 to 9.30 a.m. and from 1.30 to 3.30 p.m.

"The frequency of the oscillatory currents was estimated to be about 30,000 cycles per second, and at 50,000 volts sufficient energy was radiated from the wires so that birds in attempting to light on the wires received such a shock that they fell to the ground partially stunned. None, however, were actually killed by the current.

"Because of the lateness in getting the system into working order, qualitative rather than quantitative data only are available. However, it was very apparent that almost all the vegetables grown under the wires were better than those not electrified. These included radishes, lettuce, beets, cabbage, cucumbers, turnips, musk melons, water melons, tomatoes, and parsnips. Little or no difference could be observed in beans and peas. With the exception of these, however, the gardener in charge picked almost all the others at least two weeks earlier under the wires than under the unelectrified portions. All these different vegetables were planted in rows running east and west so that one-half of the rows were electrified and the other half not. Actual weights were obtained only in the case of tobacco. One end of a row was cut under the wires and the plants averaged 1,687 grammes per plant. One week later the other end of the row was cut and the plants averaged 1,632 grammes per plant, so that there was a gain of 55 grammes per plant, or an increase of 3.35 per cent in the crop electrified. Since the largest part of the tobacco growth occurs during the last two weeks, it is estimated that the actual increase in weight, if both ends of the row had been cut at the same time, would have been about 20 per cent."

APPENDIX.

In order to convey supplementary information to those interested in the subject of electrification of crops, and in order to answer many questions and make the lecture more complete, I hope it is permissible here to reproduce the substance of a pamphlet which I wrote and privately printed in or about 1908, and which is not otherwise accessible.

ELECTRICITY IN AGRICULTURE.

Some thirty years ago a Swedish professor named Lemström sought to elucidate the aurora borealis by trying to imitate its appearance by electrical experiments. For this purpose he produced high-tension discharges of various kinds, and sent them through vacuum tubes until he got an appearance very like those of the northern lights. Some of these experiments he conducted in his

greenhouse, and he noticed incidentally that the plants seemed to thrive under the treatment, and that the electrification thus produced in their neighbourhood appeared to do them good. He also noticed, as remarkable, the flourishing development of plants in Arctic regions, where the sunlight was very weak; and he attributed part of this growth to the influence of electric discharges.

He says that when the plants in the North of Norway, Spitzbergen, and Finnish Lapland, have resisted the frequently destructive night frosts they show a degree of development which greatly surpasses that of plants in more southern regions, where the climatic conditions are more advantageous. This rich development appears principally in the fresh and clear colours of the flowers, in their strong perfume, in the rapid development of the leaves on the trees, and their scent, but particularly in the rich harvest which different seeds—such as rye, oats, and barley—will produce, when, as before stated, they are not destroyed by the frosts. From a bushel of rye sown they will often produce 40 bushels, and from barley 20 bushels, and so forth. It is the same with grass. These results are attained although the people cultivate their soil very imperfectly, using only ploughs and harrows of wood.

He pursued the matter by careful observation, taking test plants in pairs or groups, electrifying one group—that is to say, discharging some electricity into the air above them—and keeping a similar group away from the electricity, in order to be able to compare them. Then he photographed the two groups side by side, and found in nearly all cases a marked improvement as the result of the electrical treatment. He concluded that the needle-like shape of the leaves in fir-trees, and the beard on the ears of most cereals, have the discharge of electricity as their function, and finds that they do act in this way.

This observation and these experiments of Professor Lemström were not, indeed, the beginning of the application of electricity to plant growth, because pioneer attempts had been made long before, as will be mentioned directly, but it was the beginning of a thorough and scientific treatment of the problem. Attempts of a different kind had also been made. Plates had been sunk in the ground, and a current passed between them among the roots of plants; but whatever effect is thus caused is of a totally different kind to that excited by high-tension electricity supplied to the air above them. Both in a manner are natural processes. There are natural earth currents, and these must flow among the roots of plants, though whether they produce an appreciable effect may be doubted.

There is a natural atmospheric electrification, and this must be playing an important part in many phenomena. Atmospheric electrification is responsible for the formation of rain and hail. During fine weather the electricity in the air is usually of one sign: mainly positive. When wet weather sets in, the electricity in the air usually changes sign, becoming negative. The whole subject is a large one; a great deal is known about it, and vastly more remains to be known; but meanwhile it can hardly be doubted that the electrification of the air has some effect on growing plants. For it is found that, under the influence of sunshine, electrified plants can give off electricity from the leaves; and the fact that the air is naturally electrified relatively to the soil causes all plants to be

electrified too, so that in all probability they are in a constant state of slow electrical discharge, which becomes more rapid when the sun is up. In what way this discharge of electricity from their growing tips, and hair, and surface generally, really acts, must be studied and reported on by physiological botanists; but it is natural to suppose that it cannot be without influence, and reasonable to think that the influence may be beneficial—a hypothesis which direct experiment confirms.

Possibly, in some sunny countries the effect is excessive, and might, with advantage, be moderated; but in this climate it turns out that artificial supply of electricity does increase the rapidity and assist the amount of growth. At any rate, the experiments of Lemström, which were repeated and extended by others, clearly pointed in that direction. So when, after some preliminary experiments at Bitton, Mr. J. E. Newman, of Gloucester, acting in conjunction with Mr. R. Bomford, of Salford Priors, determined to try the phenomena on a really large scale, and came to me to see if I could help them electrically, and enable them to maintain a continuous high-tension discharge for hours together each day over ten or eleven acres by means of power furnished by an oil-engine and dynamo, I very willingly assented, and set my son, Mr. Lionel Lodge, upon the job.

The method is to stretch over the field to be treated a number of wires on poles, something like low telegraph wires, but high enough for loaded waggons and all the usual farming operations to go on underneath the wires without let or hindrance. The wires are quite thin, and are supported by a few posts in long parallel spans, about 30 ft. apart. They are supported on the posts by elaborate high-tension insulators, and they extend over all the acreage under experiment, a control plot of similar land under similar conditions being, of course, left without any wires.

The system of conductors is then connected at one post with a generator supplying positive electricity at a potential of something like 100,000 volts, and with sufficient power to maintain a constant supply of electricity at this kind of potential.

Leakage immediately begins, and the charge fizzes off from the wires with a sound which is sometimes audible, and with a glow just visible in the dark. Anyone walking about below the wires can sometimes feel the effect on the hair of the head, as of a cobweb on the face. They are then feeling the stimulating action of the electrification.

The electrification is maintained for some hours each day, but is shut off at night: it is probably only necessary to supply it during the early morning hours in summer-time, and in spring-time or in cold cloudy weather for the whole day. In bright sunshine it seems unnecessary or even harmful. But at what stages of the growth of a plant the stimulus is most effective has still to be made out. Probably the earlier the better; and since in the case of wheat, both the ear and the straw is valuable, the electrification should be applied for a time each day during the whole period of growth until staling begins.

The power required to generate the electricity is very small, for although the potential is high the quantity is insignificant, and the energy is accordingly comparatively trivial. It is known that even when natural atmospheric electricity has accumulated intensely, and has become

a thunderstorm, the quantity even then is quite small, though the potential or tension is so enormous that the flashes are of astonishing violence and power while they last.

The electricity can be generated in more than one way. It can be generated by the revolving glass plates of a static influence machine, usually known in this country as a Wimshurst machine; or it can be generated by transforming up to high tension, and rectifying to one direction, the current of the revolving magnetic generator called a dynamo. The first is in many respects the simplest, and was used in the early and small-scale experiments, but it can hardly be regarded as an engineering method adapted to continuous or rough use.

The latter is the one which in the trials now to be described we have adopted.

The power is generated by a two-horse oil-engine driving a small dynamo in an outhouse of the farm. Thence the current is taken by ordinary overhead wires to the field, where they enter a suitable weather-tight hut, which contains the transforming and rectifying apparatus. The only moving part here is the "break," and if the original dynamo had been an alternator, even this might be dispensed with. The transformer is a large induction coil, specially made to stand continuous use, and its current is then rectified by means of vacuum valves in accordance with a patented device of my own.

The negative electricity is conveyed direct to earth, except when retardation is desired, or during drought; while high-tension electricity, all of positive sign, is led by a specially insulated conductor out of the shed to the nearest post of the overhead insulated wires, which are thereby maintained at continuous high positive potential.

THE RESULTS AND FURTHER DETAILS.

The following is a very brief summary of returns and information supplied to me by Mr. Newman and Mr. Bomford, showing the results from the electrified as compared with the control unelectrified plots.

SUMMARIZED RESULTS OF THE 1906 EXPERIMENTS.

BUSHELS OF WHEAT PER ACRE.

(Estimated corresponding increase in straw not measured.)

	From the electrified plot	From the unelectrified plot	Increase
Canadian (Red Fife) ...	35½	25½	40%
English (White Queen) ...	40	31	30 ..

Moreover, the electrified wheat sold at prices some 7½ per cent higher, several millers in baking tests finding that it produced a better baking flour.

The increase appears to be mainly due to better stooling. No marked difference was observable in the development of ears.

SUMMARIZED RESULTS OF THE 1907 EXPERIMENTS ON WHEAT.

RED FIFE, SPRING SOWN.

Bushels per Acre (Head Wheat).

Electrified	Unelectrified	Increase
41½	32	29 per cent

Electrified wheat brighter, and a better sample.

Increase again partly due to stooing, but this time there was better filling out of ears.

These results are for wheat alone, but a good many other crops were tried at the same time, and they appear in the more detailed statement below.

HOURS PLANT RUNNING.

1906.

10th March to 10th July, inclusive, 621½ hours on 90 days.
Average electrical pressure corresponded to a ¾-in. spark.

Current shut off after ears in bloom.

1907.

28th March to 27th July, 1,014 hours on 115 days.
Average pressure corresponded to a ¾-in spark.
Current kept on till harvest.

FURTHER INFORMATION, PARTLY FROM MR. NEWMAN.

In 1906, owing to the late delivery of some of the apparatus, the work had to be carried on with a somewhat improvised generating station at the commencement on 16th March. By the end of May, however, the installation was completed, and worked fairly continuously during the rest of the season, the current being supplied intermittently until 10th July, by which date the wheat had been in ear about a fortnight.

The complete arrangements for generation of the high-tension currents are as follows:—

Direct current, about 3 amperes, at 220 volts, is generated by a dynamo, driven by an oil-engine of about 2 h.p. The current passes from the dynamo through the primary of a large induction coil, with a make and break contact interposed in the circuit. From the secondary of the coil the high-tension current passes through the rectifiers, and then by one pole to the system of overhead wires, the other pole being earthed.

The overhead system of wires covered about 10½ acres of ground. The wires were mounted on insulators placed upon larch poles, some 15 ft. high, which were placed in rows, the rows being separated by a distance of 102 yards, and the poles in a row being 71 yards apart. Stout telegraph wire carried the current down each row, while thin galvanized iron wires, placed some 12 yards apart, were stretched between the rows, and acted as the discharge wires. In this way 22 poles were sufficient to support the wire over the 10 acres.

Roughly, only one pole per acre is required; so the inconvenience is practically nil.

The height at which the wires are taken allows a loaded wagon to go beneath.

Owing to the flexible suspension, risk of breakage to the wires is very small. (During the two years the wires have been up at Bevington, apart from a few wires broken at harvest-time by catching in top of extra high wagon load, only one wire has fallen.)

The acreage was spread over two different fields: in one field some 11 acres of wheat were under treatment, in the other 6½ acres of barley, and a half-acre plot planted with potatoes, mangolds, etc.

The wheat field was of 18½ acres extent, the remaining 7 acres were sown with English (White Queen) wheat, 1½ acres, and Canadian (Red Fife) on 5½ acres. In the

electrified part Canadian wheat occupied 2½ acres, English wheat 9 acres.

The results on the barley field, including the small plot, had to be neglected owing to the great local variations produced by the very irregular manuring the field had previously undergone. The wheat field, however, as far as one could judge, had been very uniformly treated previously.

In the wheat difference was noticeable at an early stage, the young blades on the electrified part being, in the opinion of many observers, of a darker green.

The crop was judged as considerably heavier by several practical observers, and the straw was, on an average, from 4 in. to 8 in. higher. Both experimental and control plots came into ear at about the same time, but the Canadian wheat under treatment was ready for cutting some three or four days before the control area.

The crops were gathered separately from the electrified and unelectrified plots, and the resultant yields were as follows:—

BUSHELS PER ACRE.

(Estimated corresponding increase in straw not measured.)

	Electrified	Non-electrified	Increase
Canadian (Red Fife) ...	35½	25½	39 per cent
English (White Queen) 40	31	29	..

Moreover, the electrified wheat sold at prices some 7½ per cent higher, several millers in baking tests finding that it produced a better baking flour.

No theoretical conclusions can be drawn from this fact, owing to the uncertainty existing as to what factors determine the strength of wheat, but it is interesting to note that greater strength is usually accompanied by increase in percentage of total nitrogen.

Mr. J. Kirkland, of the National School of Bakery, Borough Polytechnic, found the evidence from baking tests supported by the average of dry glens from all his tests thus:—

In the electrified ...	11.15 per cent
In the unelectrified ...	10.35 ..

The somewhat poor yield of wheat obtained from the unelectrified portion of the field is probably explained by a deficiency in lime, which has now been rectified. Further, the wheat was spring sown, and Red Fife, under this condition, does not usually yield good crops. The experiments are being repeated upon wheat during the present season, and strawberries are also under treatment once more.

In 1907, wheat was grown again in the 1906 wheat field. Current cut off from most of the barley field, which was down to clover and rye grass. 8½ acres in an adjoining field planted with strawberries (Stirling Castle) in March, approximately 2½ acres having a wire network erected over them. Mangolds were planted between the strawberry rows.

The wheat field was during the early spring given a dressing of lime to cwt. to acre, 4 cwt. to acre bone meal drilled in, the unelectrified part given 1½ cwt. sulphate of ammonia, and the electrified part ¾ cwt. Barley had been grown on the strawberry field in 1906, and this was

given 10 tons to acre of farmyard manure, which was ploughed in.

RESULT OF CROPS, 1907.

WHEAT.

(Variety, *Red Fife*, Spring Sown.)

7½ acres unelectricified	gave 239 bus., 38 lb. Head Wheat, 15 bus., 1 lb. Tail
11 .. electricified	.. 455 bus., 50 lb. .. 17 bus., 27 lb. ..

Or, summarizing as before—

BUSHEL PER ACRE (HEAD WHEAT).

Electricified	Unelectricified	Increase
41'4	32	29 per cent

Electricified wheat brighter and a better sample. Increase due to better stooling and also better hilling out of ears.

STRAWBERRIES.

During the first year, the crop was necessarily very small, and was picked chiefly to see if any increase had been obtained. The result showed a 35 per cent increase. Earlier ripening was also observed.

ANALYSIS OF SAMPLES OF THE FRUIT TAKEN FROM BULK.

Mangolds.—It was found impossible to weigh either the whole or a part of this crop. Estimated increase (from number of cartloads removed), 25 per cent. Analysis showed an increase in the sugar where electricified, but the results varied considerably.

Small plots of raspberry canes showed a marked improvement in growth.

Small plots of tomatoes also showed large increase in the crop.

(A curious point about the raspberries was that the foliage and fruit on the old canes showed no difference, but that the new growth, particularly after the old wood was cut back, showed an enormous difference in favour of the electricified. Manurial treatment exactly similar.)

Those interested in the experiments are much indebted to the enthusiastic co-operation of Mr. Bomford, of Bevington Hall, Salford Priors, near Evesham. It may be interesting to note that it was at a farm belonging to Mr. Bomford's father that the first steam ploughing in England was done.

Professor Lemström is undoubtedly the pioneer in this sort of work; though circumstances connected with the natural electrification of the atmosphere, and with the discharge of electricity from various surfaces, have been pertinaciously examined by Professors Elster and Geitel.

ON THE HISTORY OF THE SUBJECT.

Professor Lemström published his results with full details and illustrations, both of the apparatus used and of the appearance of some of the resulting crops, in a small book called *Electricity in Agriculture and Horticulture*, published in English by the Electrician Company in 1904, and it is well worth referring to.

He quotes earlier attempts—one as far back as the year 1746—and describes his own early experiments in the

University of Helsingfors, conducted in cardboard compartments in front of a south window, in May and June, 1885.

His only mode of electrification, however, was the old influence machine based on the type of Holtz and Wimshurst, though on account of their inconveniences during prolonged use, he devised a cylindrical type, which he found on the whole more trustworthy; and with it he obtained striking success; for instance, 37 per cent increase in the yield of strawberries.

No doubt most of the difficulties connected with experiments in this subject have been due to the difficulty of supplying the electricity in a continuous and convenient manner. The use of the rectifying valves was expected to get over all these difficulties, but the necessary experience cannot be obtained without large-scale continuous running for a good many hours each day.

In 1907 a paper was read by Mr. J. H. Priestley, B.Sc., before the Bristol Naturalists' Society, and is published in their *Proceedings*, Fourth Series, Vol. I. Part III, 1907; and from this paper the following account is taken:—

One of the earliest modes of supplying electricity to plants, etc., was that of the Abbé Berthelot in 1783. He raised a head of metallic points in the air, in the manner of a lightning conductor, and made it terminate in a series of discharge points just over the plants. He states that the use of this apparatus was invariably accompanied by an improvement in the appearance of the vegetation and by an increase in the fertility of the plants.

An opposite or control experiment was made by Grandea in 1879, when he protected a plant from atmospheric electricity by means of a wire cage, and showed that its development was greatly retarded.

Other experiments have done the same thing and made careful measurements of the results, which are all in the same direction.

A summary of other workers in these directions, as well as of the less satisfactory methods of supplying electricity in the soil, is also contained in Mr. Priestley's paper.

The work of Professor Berthelot in France, at the Station for Agricultural Chemistry established at Mendon, must be specially noted. He tried the effect of a silent discharge, and particularly of atmospheric electricity upon plants.

He compared the growth at the top of a 28-metre tower with that of plants growing at the foot, and considered that greater growth at the higher level was largely due to the potential gradient in the atmosphere.

Berthelot considers that the clue to advantage of the electric discharge is to be found in an entrance of atmospheric nitrogen into the plant metabolism, but suggests that this is due not only to the formation of oxide of nitrogen, but also to the combination of gaseous nitrogen with carbohydrates within the plant.

Dr. Cook, of Bristol, likewise obtained an increase in the rate of growth by the use of an overhead discharge on a small scale.

EXPERIMENTS AT BITTON IN 1904.

During the winter of 1904 Mr. J. E. Newman installed a small trial apparatus, consisting of a small influence machine of the Wimshurst type and overhead discharge wires, at the Golden Valley Nurseries at Bitton, near Bristol. The

wires ran about sixteen inches above the tops of the plants, or above the rows of tomatoes in the glasshouses, and short pieces of fine wire, with the free ends pointing downwards, acted as discharge points.

From 7th March to 26th July the machine was running during 108 days for a period of 9·3 hours daily, principally at night.

In all cases control plots were provided, which, as far as practicable, were under identical conditions.

The crops from the electrified and control plots were gathered and estimated separately, usually by weighing. The result was as follows:—

- Cucumbers, 17 per cent increase.
- Strawberries (five-year plants), 36 per cent increase.
- Strawberries (one-year plants), 80 per cent increase, and more runners produced.
- Broad beans, 15 per cent decrease, but ready for picking five days earlier.
- Cabbages (spring), ready for picking ten days earlier.
- Celery, 2 per cent increase.
- Tomatoes, no difference.

A somewhat similar installation was also working in Mr. G. R. Newman's vegetable garden near Gloucester. Here a somewhat higher voltage was given by the influence machine, and the discharging points were kept five feet above the ground. In this case—

- Beet showed 33 per cent increase.
- Carrots showed 50 per cent increase.

The amount of sugar in the beets was determined as follows:—

- The electrified yielded 8·8 per cent total sugar.
- The unelectrified yielded 7·7 per cent total sugar.

The results of some small trials with wheat, also made at Gloucester, were very favourable, so Mr. Newman decided to try the effect of the overhead discharge system on wheat and barley on a larger scale.

Thanks to the interest taken in the work by Mr. R. Bomford, of Bevington Hall, near Evesham, Mr. Newman was enabled to use some forty acres of this estate for experimental work in 1906, and experiments commenced on this ground in the spring of that year, and are still being continued.

Some twenty acres of this ground were beneath the discharge field, and, as it was necessary for practical purposes to have the discharge wires at a considerable height, the very high-tension current required was obtained by means of an induction coil and valve rectifiers upon the system devised and patented by Sir Oliver Lodge, who very kindly lent the necessary apparatus.

It was very largely owing to the generosity of Sir Oliver Lodge, and the advice and help of Mr. Lionel Lodge, that Mr. Newman was able successfully to complete the necessary installation and to carry out the experiments.

Since this date Mr. G. R. Newman has established a large installation at his nurseries at Bitton, near Bristol.

Inquiries may be addressed to Mr. J. E. Newman, General Manager of The Agricultural Electric Discharge Company, at 85 Park End-road, Gloucester.

PROCEEDINGS OF THE INSTITUTION.

ORDINARY MEETING OF THE 12TH FEBRUARY, 1914.

Proceedings of the 562nd Ordinary Meeting of the Institution of Electrical Engineers, held on Thursday, 12th February, 1914—Mr. W. DUDELL, F.R.S., President, in the chair.

The minutes of the Ordinary Meeting held on the 22nd January, 1914, were taken as read, and confirmed.

The list of candidates for election and transfer approved by the Council for ballot was taken as read, and it was ordered to be suspended in the Hall.

Donations to the *Library* were announced as having been received from The Association of Mining Electrical Engineers, W. K. L. Dickson, The Institute of Chemistry, M. W. Jenkinson, Dr. A. E. Kennelly, The Manchester Steam Users' Association, Messrs. Ridsdale & Co., Messrs. E. & F. N. Spon, Ltd., A. J. Stubbs, Dr. S. P. Thompson, F.R.S., and the United States Department of Commerce; and to the *Museum* from E. S. Shoults, to whom the thanks of the meeting were duly accorded.

A paper by Mr. Roger T. Smith, Member, entitled "Some Railway Conditions Governing Electrification" (see page 293), was read and discussed, and the meeting adjourned at 10 p.m.

DISCUSSION ON

"ELECTRICITY SUPPLY OF LARGE CITIES."*

NEWCASTLE LOCAL SECTION, 8TH DECEMBER, 1913.

Mr. C. VERNIER: I think the supply of electricity for London is one of the most important and urgent problems before us at the present time. When we consider that London accounts for very nearly one-third of the present consumption of electrical energy in the United Kingdom, it is obvious that the importance of this question cannot be overrated. At the same time, it is not one of the easiest problems to solve—not from the engineering point of view, but more as a question of practical policies—since the present supply is given by no less than 64 power stations, each, with few exceptions, supplying small but very densely populated districts. The question is also further complicated by the fact that some of the undertakings are owned by municipalities and others by companies, and by the fact that the London County Council has the right to purchase the company-owned undertakings in 1931, but not the municipal ones.

Turning to the address, I think it is well to bear in mind that the author makes some important assumptions. For instance, he assumes that approximately 10 per cent interest should be provided on the capital invested, viz. 6 to 8 per cent for the investors, and 3 to 4 per cent for the sinking funds. Few will be found to question the soundness of this view, but I would merely point out in contrast that the average interest earned on the whole of our electricity undertakings in this country is about $4\frac{1}{2}$ per cent, while the average placed to sinking and depreciation funds is only 2·6 per cent. Fig. 5 is very interesting, and shows that electrical energy is now being sold in London at a price which does not produce what the author has laid down as a satisfactory return upon the capital invested, while Berlin and, in a lesser degree, Chicago show up much better in this respect. The net result of the proposal outlined in Table VI is a possible annual surplus of £200,000, and a reduction of the total costs from 2·34d. to 1·90d. (item 21). To achieve this result it is necessary to spend £1,709,000 (item 22). If no better result is to be obtained, I myself do not think it would be worth while spending this large sum, and particularly facing all the difficulties. Fortunately our hope of a satisfactory solution of the London electricity supply problem does not rest upon a mere re-arrangement of the existing generating plants, but much more upon its huge prospective traction and heating and cooking load, which the author has completely disregarded in his calculations.

Turning to the question of the cables, I am somewhat surprised that Dr. Klingenberg, after boldly suggesting 100,000-volt three-phase underground cables for his long-distance transmission, thus going a good deal further than any previous suggestion that I have seen—I refer to the proposed length of underground transmission and not to the voltage—should have stopped at 20,000 volts for his ring and connecting mains. I am convinced that to-day it would be a mistake to consider anything less than 40,000-volt to 50,000-volt cables for any new scheme on the scale

of that for London; and for the same load capacity a considerable saving could in this way be obtained. By using five 40,000-volt cables in place of ten cables to connect the ring mains to the power station, and two 40,000-volt cables in place of three 20,000-volt cables for the ring mains themselves, the estimated saving would be about 40s. per kilowatt on Estimate A (page 135). With regard to the proposed scheme for supplying London direct from the coalfields distant 100 miles or so, I think this question cannot be considered merely from the point of view of the possible saving that might be obtained in the cost of the electrical energy delivered in London. The question of paramount importance is the security of the supply. For this reason I think that a direct overhead transmission is quite unsuitable, except perhaps for a partial supply. If high-voltage transmission lines are ever run to London, it will be to link up the power stations there with other parts of the country. Fig. 12 suggests quite well the idea of a ring main round the whole country, with London doing its share in improving the utility and other factors of our generating plants. When we come to consider 100,000-volt underground transmission, I agree with Dr. Klingenberg that there is no difficulty in constructing single-core cables for three-phase working at that very high pressure. I should be glad, however, if he would give us some idea of what he estimates the charging current would be for a 100-mile underground transmission at this voltage and 50 frequency, and also state how he would propose to deal with it—if by loading coils at intervals throughout the route, the cost of these cannot be neglected. There are other important points arising out of the use of underground cables at such high voltages, particularly the various losses such as copper losses, due to the large capacity currents, dielectric hysteresis—both of these are continuous losses—and sheath losses arising from the use of single-core cables; there is also the difficulty of keeping the lead sheaths insulated so as to prevent circulating currents. All these would be by no means negligible on such a scheme. In conclusion, I think it would be very useful if we were to adopt the "utility factor" in our statistics. It is the only factor which enables one to determine at a glance how remuneratively the capital expended on the generating plant is being employed. It combines load factor, diversity factor, efficiency of distribution, and stand-by plant; and in view of the advisability of urging the centralization of our generating plants, it is a factor which has to be carefully watched.

Mr. H. L. RISLEY: I think it should be clearly understood that Dr. Klingenberg is only putting forward certain propositions, and that his suggestions need not necessarily be considered the correct policy as regards the bulk supply of electricity to London. With regard to the 64 stations in operation in London, I think it is probably correct to state that a very large majority of them should be scrapped, as they are nearly all obsolete and have no adequate supply of condensing water easily accessible. It seems to

* Address by Dr. G. Klingenberg (see pp. 123 and 230).

Mr. Vernier

Mr. Risley

Mr. Risleley. me that too much attention has been given to the question of the supply of coal. I consider the provision of water for condensing purposes to be at least an equally important question, because it is much more feasible to transport the coal required than to find a proper supply of condensing water. Then as regards having a power station at the coalfields, this does not appear to me to get over the trouble, as everybody knows that it is quite possible for the pitmen to go on strike; also there is the possibility of fires and floods, and many other causes which would shut down the pits and thus affect the power station. In my opinion there is no advantage in having a power station at the pit's mouth. Moreover, where is there a pit or a group of pits which would be sufficient to supply the electrical requirements of London? I consider a better way would be to place the stations near the Thames and to run the main feeders east and west, not north and south as suggested by the author. There would be no difficulty in getting the colliers up the river as far as the bridges, and I do not think it would be impossible to get specially constructed steamers perhaps as far as Chiswick, since the Gas Light & Coke Company run fairly large boats up as far as Westminster Bridge without trouble, and Messrs. Thornycroft have sent down some fairly large craft from Chiswick. If, however, the colliers could not get up, no doubt specially constructed barges of, say, 5,000 tons capacity could be towed up from the coal-shipping port.

Dr. Klingenberg's remarks as to the difference in the total costs and operating costs at Berlin and Chicago are very interesting. I note that the Edison Company of Chicago has made a better bargain with the local authorities than the Berlin company; the Chicago company only pays 3 per cent of the gross receipts to the municipality, whereas the Berlin company has to pay 10 per cent. Possibly, however, it costs Chicago a lot of money to get this low rate; the sum should be capitalized and included in standing charges. I do not think the author's intricate formulae would be of much use to engineers, but it is interesting to see the clear way in which the author brings out his results. In my opinion, at the low tariff that will have to be adopted to make the use of electricity universal there is not much chance of obtaining such an adequate return on the capital as would readily induce the public to subscribe. I think the ultimate solution of the administration of electricity supply in the metropolis will be a non-political board constituted on the lines of the Water Board or the Port of London Authority.

Mr. C. TURNBULL: At the end of his address the author mentions the recovery of by-products from coal. The gas-engine plant at Accrington has shown that the recovery of by-products may be successfully carried out in connection with the generation of electricity. In view of this experiment and other work now going on in this direction I think that we should hesitate before replacing existing plant by large power stations which themselves might be obsolete in a few years time when better methods have been introduced for the more efficient utilization of coal. On the other hand, it is very necessary that extensions over and above the capacity of existing plants should be co-ordinated, so that they will fit in with the large schemes which must eventually come into operation in London and other large cities.

Mr. W. McLELLAN: The wholesale supply of electricity to London is not so much an engineering problem as a political one, and it is becoming increasingly difficult every day on account of the new power stations which are being erected by the railway companies and other bodies. A previous speaker referred to the possibility of erecting at a coal-mine the generating station for supplying London; as Mr. Risleley has pointed out, however, this would be an exceedingly risky thing to do, because the coal-mine might be shut down due to accidents or strikes. Moreover, no individual mine would be large enough to supply the ultimate electrical requirements of London. At the present time something like 17½ million tons of coal are sent each year to London, of which only about ¼ million tons are used for the purpose of generating electrical energy. If electrical engineers are right in assuming that in the future the bulk of the power and lighting (and in some cases possibly the heating) requirements will be provided electrically, it will be seen that no single coal-mine would be sufficient to provide the large amount of coal required.

Mr. J. A. ANDERSON: In regard to depreciation and reserve, Dr. Klingenberg gives a figure of 3-4 per cent on the whole of the capital expenditure. This is more than enough for a system which is kept in first-class repair. The only parts of the system that would warrant this figure are the power stations, which may have to be scrapped in 20 or 30 years' time. As far as cables are concerned, if a company sets aside 20 per cent of the cost of the cables as a reserve fund, in 20 years' time it should have enough to meet any large replacement that may then be necessary. As to sub-station plant, it is hardly conceivable that many large replacements will have to be made within any short period, and it is not necessary to set aside any large reserve for this purpose. In connection with a general supply of electrical energy to London, a board appointed by those interested, as suggested by Mr. Risleley, appears to me to be the best means of obtaining the results that we should like to see. I think we shall all agree that a central supply authority is very essential from the point of view of economy.

Mr. H. G. A. STEEDMAN: We should have followed the author's figures more easily if he had adopted orthodox units instead of such units as "centi-shillings." A little more explanation might also have been given when defining such factors as (a) and (b) in Equations 4 and 5, and $1/n_{\text{eff}}$, etc. When the comparisons with London generating stations were made, are we to understand that those at Lots Road, Neasden, Greenwich, etc., were excluded? With regard to the capital cost of generating plant and network respectively, the author draws attention to the fact that the cost per kilowatt decreases rapidly as the capacity of the generating plant increases, but that the contrary effect applies to an increase of the capacity of the network. Against this, however, must be set considerable advantages and economies appertaining to large networks. I should be much interested to have further explanation as to the assumptions which were made by Dr. Klingenberg in preparing Fig. 4, which diagram, if of general application, should be of considerable value. Another important observation is made on page 131 in connection with the utility factor, showing that, within the limits stated, the selling price can be reduced

by more than 3 per cent for each 1 per cent advance made in utilization without alteration to existing plant. The author's application of his analyses to the practical case of what may soon be one of the most important problems confronting electrical engineers, viz. the systematic supply of energy in Greater London, merits most careful consideration.

Mr. H. M. TAYLOR: The author has dealt with the existing conditions of electricity supply in three cities. He takes London as one example. The position of electricity supply in London, is admittedly unsatisfactory, and many attempts have been made to remedy it; the author does not refer, however, to these attempts, nor does he include the greater part of the London traction supply. As the figures which he gives relate to 1910-11, the recent growth of the traction supply detracts from the value of those figures. In the case of Berlin he includes traction. Again, in Table III he gives the various percentages of lighting, power, and traction. Are we to suppose that electric lighting in London at the present time accounts for 61 per cent and traction for 12 per cent of the total number of units supplied? The author takes for London the year 1910. I therefore suggest that the selling prices and other financial results given for Berlin, Chicago, and London are incomparable.

I propose to consider another English city, namely, Manchester. One reason why I choose Manchester is that although the population is not comparable with that of Berlin, the number of units sold per head of population is not very different. The comparison is as follows:—

	Manchester.	Berlin.
Population	750,000	2½ million
Number of power stations ...	3	6*
Capacity of plant installed ...	58,800 kw.	137,000 kw.
Average size of stations ...	19,600 "	23,000 "
Capital expenditure	57,410,420s.	160,426,000s.
Sinking fund, etc.	18,435,400s.	30,380,000s.
Real value	38,975,020s.	130,046,000s.
Cost per kilowatt installed ...	243s.	356s.
Cost of mains per kilowatt ...	352s.	594s.

It will be noticed that the capital outlay on the Manchester power stations is 40 per cent of the total outlay, against 38 per cent in Berlin, leaving for the network, etc., 60 per cent and 62 per cent respectively. The working results for the two cities are:—

	Manchester.	Berlin.
Total peak load	44,912 kw.	94,600 kw.
No. of units generated	136,820,180	274 million
No. of units sold	104,346,895	216 million
Lighting and power	71 per cent	69 per cent
Traction	20 "	31 "
Average price obtained	8·92 centishillings	15·8 centishillings
Working costs	4·83 centishillings	5·067 centishillings

In order to make the figures comparable I have deleted from item 40, Table III, the item for municipal participation. The above comparisons show that British practice is not so very far behind that of other countries.

* On page 124 the author says that a number of other stations are still working in Berlin.

Mr. J. WRIGHT: I think the author brings out very clearly one point, which forms to a great extent the basis of his figures. I refer to the development of large generating sets, in which the steam turbine has played a very important part; but for the progress that has been made in this direction Dr. Klingenberg could not have shown the figures which he has. This development has brought about a reduction both in operating costs and in capital expenditure; thus he truly states on page 125 that it is the number and not the size of the units that controls the costs. From the figures which he gives with regard to the London undertakings it is obvious that the figures would be improved considerably if some of the smaller power stations were done away with. It is rather surprising to find that the Berlin undertaking seems more economical than the Chicago undertaking, although no doubt the purchase conditions existing in America account for this. The author also states that the fuel consumption of the Berlin undertaking shows a marked superiority over those of Chicago and London stations. It would be rather interesting to know what section of the plant should be credited with this efficiency. Is it the boiler house or the engine-room? I think it must be the boiler house, as I am not aware that any of the German turbo-generators have shown any remarkable improvement in efficiency over that obtained in this country or America. I can, of course, understand that the combined London stations will not give good figures as regards steam consumption, particularly over the period which Dr. Klingenberg has taken, as up to that time many of the smaller stations were still operated with reciprocating sets which were not efficient. I do not therefore consider that the Berlin and London figures can be compared. It would be interesting to know what would be the maximum size of unit that Dr. Klingenberg would suggest installing in his station. When the stand-by plant required is taken into consideration, the size of the sets must affect to some extent the capital expenditure involved. With regard to the position of the station, and taking Dr. Klingenberg's remarks into consideration, it would seem that the ideal place for a station for London is near a colliery and an adequate water supply; in addition, such a station should be run in connection with a by-product plant, and be in an area where a traction load is likely to be developed. Such a site would of course be difficult to obtain, but the whole success of any London scheme seems to depend on being able to get a traction load. With regard to the author's estimates for coal, I notice he shows only a difference of 3s. 6d. per ton between coal at the pit-head and coal delivered into the bunkers in London. I think the difference would be rather greater, unless, of course, the much-heard-of Kent coal is used.

Mr. R. M. LONGMAN: One of the chief points in the address are the equations for cost, etc. I do not think they have been arranged as clearly as they might have been, although the author has certainly obtained them in the correct way. With reference to Chicago, the fuel costs are rather high. I do not consider that American steam-turbine practice is as good as that in this country. They do not get such good efficiencies, that is, measured in lb. per kw.-hour. When we have got more big stations, I think we shall be able to show even better figures. The high capital cost of the Chicago undertaking is partly due to the fact that a large number of small stations had to be

bought up. It must be remembered that in America money is worth less and is more plentiful than in this country. On page 137 why should the cost of the power station be higher with overhead transmission than with cable transmission? Again, 80,000 kw. is far too small for the main station. At Chicago a 20,000- or 30,000-kw. station was erected and immediately afterwards the construction of one of 120,000 kw. was commenced. The author has not referred to the traction load, as he might reasonably have done. One cannot help feeling rather sorry at the present time that the railways are putting down more of these really small stations. There is no set at present in London above 6,000 or 7,000 kw. capacity. Indeed, 5,000 kw. seems to be about the limit. It is a very great pity that such small units are being chosen. The arguments do not necessarily apply only to London. If a number of local authorities would supply the money in the form of debentures, it would be possible to have really large stations containing sets of 20,000 or 30,000 kw. capacity. The author has shown the possibility of using cables at 100,000 volts. There is no technical reason why 60,000- or even 100,000-volt cables should not be installed; but a large amount of energy would have to be transmitted so as to keep the cost per kilowatt to a low figure.

Mr. A. H. W. MARSHALL (*communicated*): I have not been able to follow the formula on page 126 dealing with the operating costs. Perhaps the author will state what the terms "a" and "b" represent in Equations 2 and 3, and also explain Equation 5, which represents the characteristic costs for an entire plant. Without a proper understanding of these expressions it is impossible to appreciate the full value of the investigations which Dr. Klingenberg has made into the cost of electricity supply in Berlin, London, and Chicago. The term "utility factor" (*n*) which forms the basis of the calculations is of course the plant load factor multiplied by the efficiency of distribution (*m*). Its connection with the load factor and spare plant, as given in Equation 6 on page 128, is very interesting. There appears to be no direct comparison in the paper between the selling prices in the three cases with reference to the respective load factors; and this after all is what is required in order to know whether energy is relatively dear or cheap. From the figures given, the load factor at Chicago appears to be 36 per cent and the selling price 100d. per unit; Berlin 20 per cent and 19d. per unit; and London 19 per cent and 234d. per unit. These prices are astonishingly high, even with the relatively poor load factors.

In his estimates for the reconstruction of the London undertakings, I think the author would have done well to assume a greatly increased traction and power load, comparable as regards the proportion of lighting, traction, and power, with that in Berlin. His figures would look very much better if they took into account the large extensions which a reconstruction of the undertakings with the improved facilities would undoubtedly bring about. The addition of further traction and power load would improve the load factor and thus the utility factor; and an improvement in the utility factor would react on the price and develop a vastly greater market, tending on the whole to improve the business in an accumulative manner. If a reasonable allowance were made for such an increase of load, the scheme of reconstruction would be more attrac-

tive to investors. As it is, the figures show a saving of £260,000 on an expenditure of about 1½ millions of capital—a saving of about 15 per cent after paying interest on new capital. It should be noted, however, that the rate of interest allowed is only that obtained at present, which owing to the nature of the business is perforce lower than the holders of the existing capital desire. Additional capital would require a higher rate of interest and probably a more liberal depreciation charge than that allowed. It would probably be well to reduce the surplus by a figure representing a further 5 per cent on the new capital, which would leave about £174,000 to be divided amongst the 25 existing undertakings as their share in the benefits of any reconstruction scheme. I do not know how far this would be sufficient when it is considered that these 25 undertakings have at present a capital of £21,763,000, and that the legal and other difficulties necessary to bring about such a change as is proposed would be immense. With, however, an increased power and traction business—which would undoubtedly be developed if the reconstruction were undertaken on the lines suggested—and a utility factor approaching that of the power companies in this part of England, the estimates would make a much more attractive proposition for the reconstruction scheme. In regard to items Nos. 18 and 19, Table VI, the low-tension network losses after conversion are less than they were previously. I do not see why this should be so, seeing that new cables are being laid down, and presumably the existing feeders will remain for distribution purposes. On page 136 Dr. Klingenberg proposes purchasing a strip of land for the main transmission lines at about £11 per acre. I consider that such a figure is far too low.

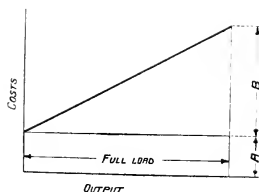

Dr. G. KLINGENBERG (*in reply; communicated*): Mr. Vernier does not consider the estimated result (item 26, Table VI, page 141) of replacing 22 of the existing power stations by one large station sufficiently encouraging to warrant its being carried out on the lines which I have indicated. It appears to me that he has omitted to take account of the fact that item 14 in Table VI includes, apart from depreciation, 6 per cent, or £102,540 per annum, on the new expenditure necessary to effect the reconstruction, and that after paying 8 per cent (interest and depreciation) on the existing capital, £362,540, i.e. about 21 per cent per annum, would therefore be available for dividends on the new expenditure. For a solution of the problem Mr. Vernier looks to the combination of the existing stations with a traction load; but it must be admitted that such an amalgamation is out of the question unless the economy of the stations giving a general supply has reached that of modern traction power stations. The solution proposed by Mr. Vernier is therefore subject to such alterations as those which I referred to in connection with Table IV. I omitted electric heating and cooking because at present this load is exceedingly small compared with the other loads which I have considered, and in consequence there are at present no reliable data of general value with regard to the load curve, diversity factor, etc. I should therefore have had no reliable basis for my figures as in the case of light, power, and traction.

I have read with great interest Mr. Vernier's views with regard to the pressure that should be used in the case of cables laid in cities; such an opinion expressed by an engineer with his experience will certainly carry great weight.

My conservatism as regards the pressure (20,000 volts) to be used for the cables in the London area was mainly due to insufficient acquaintance with the exact local conditions. A pressure of 40,000 or 50,000 volts will in all probability necessitate the use of single-core cables, which are more expensive to lay than three-core cables; further, with such pressures the space required for the sub-stations rapidly increases. As the laying of the cables and the space required for sub-stations generally form a large proportion of the total cost in the case of large cities, the advantage of the extra high pressure is more quickly nullified in such cases than with cable systems in the open country. The charging currents for the 100,000-volt trunk cables are very large. With a frequency of 50 \sim and 3 single-phase cables per circuit of the size which I have taken, the power required for charging amounts to about 700 k.v.a. per kilometre. To avoid this I have assumed that choking coils are provided at the end of every 50 kilometres (about 30 miles) of such a capacity that they balance 80 per cent of the charging current. These choking coils, together with the necessary switch-gear, increase the total cost of the main and auxiliary cables by about 3.5 per cent. A large amount of energy is lost in such cables compared with the cables used up to the present time, but owing to their large carrying capacity their efficiency is quite satisfactory even in the case of long distances (see the differences in the efficiencies at various distances in Fig. 10).

I do not consider Mr. Riscley's and Mr. McLellan's objections to the power station at the pit's mouth, namely, the risk due to strikes, are justified. In the first place, I take it for granted that a large city will obtain its electricity supply from several power stations, and therefore from more than one colliery. Secondly, a strike at such a colliery would not endanger the electricity supply unless other collieries and the transportation companies also took part in the strike and thereby stopped the coal supply altogether. But this it must be admitted is a risk which has to some extent to be faced wherever the power station is placed, whether near or distant from the respective cities.

Mr. Stedman's and Mr. Marshall's requests give me a welcome opportunity for further explanations of my equations for the cost characteristic. The equations are based on the simple fact that the relation between the output and the charges affecting the selling price of electrical energy is approximately as shown in the diagram here-
with:—

namely,—

$$\text{running costs} = A + B \times \text{output} \div \text{full load} \quad (7)$$

A and B being constants, of which A represents the cost of operating and maintaining the plant at no load (no-load losses, standing capital charges, etc.), and B the difference in the costs between no load and full load.

Let n = utility factor over a year,

L = full-load capacity of the plant,

K = yearly running costs per kw.-hour,

$a = A/L$ = no-load costs per kilowatt,

$b = B/L$ = increase of costs per kilowatt.

Then Equation (7) can be written as follows:—

$$n \times 8,760 \times L \times K = 8,760 \times L \times a + n \times 8,760 \times L \times b \quad (8)$$

or the yearly running costs per kw.-hour—

$$K = \frac{1}{n} \times a + b \quad (9)$$

For machinery such as boilers, generators, etc., the constants a and b can easily be determined by actual tests with varying loads. Other items such as repairs, general expenses, etc., have to be found from the yearly statistics. Generally the statistics for these items only give the value K at a certain utility factor n ; to determine therefore the absolute values of a and b , it is necessary to estimate in such cases the ratio $a:b$ (see Table V, page 140). The relationship is not quite so simple for finding the average cost of fuel for a power station with a number of sets, because apart from the characteristic of each individual boiler, turbo-generator, etc., the no-load costs depend on the number of hours for which each unit has been run during the whole year.

Let K_0 = average annual cost for fuel per kw.-hour generated.

L_1, L_2, \dots = full-load capacity of the various sets,

s_1, s_2, \dots = yearly running hours of the various sets,

Z = number of sets installed,

n = utility factor of the power station,

a_0 and b_0 = constants in connection with the fuel consumption, as explained above.

Then Equation (8) reads as follows—

$$n \times 8,760 \times \Sigma(L) \times K_0 = 8,760 \times \Sigma(s \times L) \times a_0 + n \times 8,760 \times \Sigma(L) \times b_0 \quad (10)$$

Therefore—

$$K_0 = \frac{1}{n} \times \frac{\Sigma(s \times L)}{8,760 \times \Sigma(L)} \times a_0 + b_0 \text{ per kw.-hour} \quad (11)$$

If all the sets are of equal size —

$$K_0 = \frac{1}{n} \times \frac{\Sigma(s)}{8,760 \times Z} \times a_0 + b_0 \text{ per kw.-hour} \quad (12)$$

It will be seen that the expression $\frac{\Sigma(s)}{8,760 \times Z} = f$, represents a well-known factor, namely, the ratio between the actual running hours per annum of all the sets and the maximum possible number of running hours. With this simplification the average cost for fuel in the power station is expressed by the equation—

$$K_0 = \frac{1}{n} \times f \times a_0 + b_0 \text{ per kw.-hour} \quad (13)$$

Dr. Klingenberg

From the definition given above, it is evident that f lies between a maximum value $= 1$ and a minimum value $= n$.²²

In the calculations for my address I assumed in all cases for f the mean of the limiting values, namely, $f = \frac{1}{2}(1 + n)$. Substituting this in the above equation we obtain—

$$K_w = \frac{1+n}{2n} \times a_w + b_w \text{ per kw.-hour} \quad (14)$$

This is identical with Equation (3) on page 120 in my address if the constants there given are multiplied by the cost of fuel.

As regards Fig. 4, the load factor diagram for any desired combination of light, power, and traction, the values taken have been obtained by superimposing in various combinations the fundamental values for light, power, and traction, from the load curves of Fig. 1. Examples of such superimposed curves are given in Figs. 2 and 3, and it will be found that the load factors in those figures are identical with the values obtained from Fig. 4 at the respective values of r_2 and r_3 .

I have read with interest Mr. Taylor's data relating to Manchester, which are characteristic of a plant with exceptionally low capital costs (the total being 595s. per kilowatt installed) and average overall efficiency (about 7 per cent); but as I have previously explained (see page 243) the purpose of my address was not to compare power plants on the basis of the best records of working costs, and I will therefore refrain from further remarks on those figures.

The difference in the economy of the power stations in Berlin and Chicago is, I believe, due to a certain extent to less efficient machines, but mainly to the higher superheat used in Germany. According to my information it was the practice in Chicago at the time to which the figures in my

²² Further details in connection with the influence of this running-hour factor (f) on the cost of fuel in power stations will be found in my book dealing with the design of large power stations.

address refer not to exceed a temperature of 250° C., whereas in Berlin steam temperatures between 300 and 350° C. were used.
